### Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

ELSEVIER BOOK AID

Sabre Foundation

The first edition of this text was dedicated to my family. Grandma Rose helped awaken my curiosity in medicine and my parents supported it. My wife Kay and my children, Stacey, Matthew, and Dana provided the encouragement that was needed to persist and complete the book itself.

The second edition was dedicated to all my colleagues in family practice here in Midland who were so gracious in covering call for me during my travels and while writing.

As this third edition is published, medicine is in turmoil. We are trying to find direction. Our care is being driven by evidence-based medicine. A cost-effective approach to provide that care is of paramount importance. Finding a way to enable care for all and determining methods to support the aging population have gained center stage importance. With this in mind, this third edition is dedicated then to my two grandsons, Daniel and Ryan Maura. They are the future. They and their generation will need to pull and mold the best of the past to create a new world of healthcare to address these issues. It is for them that we strive to do our best. It will take their best to allow us to continue to provide the highest quality of medical care in the world.

### John L. Pfenninger, MD

As they should be, the first and second editions were dedicated to our families, friends, and colleagues. They both inspired and tolerated us through this process, again and again. Likewise, this edition is dedicated to them.

This edition is also dedicated to primary care clinicians everywhere who have endured practicing in our current healthcare system; all of us know what that means and it has not always been nurturing and supportive. As we continue to endure, adapt, and persevere, this book is dedicated to those who continue to do the right thing, what's best for our patients, their families, our profession, and the healthcare system. Even though future healthcare systems are likely to be more complicated, new technologies and procedures will evolve that can keep it fun and exciting. And my prediction persists that patient outcomes and satisfaction as well as healthcare systems will be enhanced when as many procedures as possible are provided by primary care clinicians.

Grant C. Fowler, MD

### **CONTRIBUTORS**

### Suraj Achar, MD

Associate Clinical Professor, Associate Director of Sports Medicine, University of California–San Diego, San Diego, CA

### Christopher F. Adams, MD, MBA

Fellow of Sports Medicine, University of Missouri–Kansas City, Kansas City, MO

### Olasunkanmi W. Adeyinka, MD

Assistant Professor, Department of Family and Community Medicine, University of Texas Medical School at Houston; Medical Director, UT Physicians–Family Medicine, Houston, TX

### Scott Akin, MD

Medical Staff, Contra Costa Regional Medical Center, Martinez, CA

### Haneef Alibhai, MD, CM, CCFP, FCFP

Medical Director, MD Cosmetic & Laser Clinic, Abbotsford, Vancouver, BC, Canada

### Philip J. Aliotta, MD, MSHA, FACS, CPI

Chief of Urology, Sisters of Charity Hospitals; Attending,
Department of Urology, School of Biomedical Sciences and
Medicine, SUNY–Buffalo; Attending and Director of Pelvic
Floor Disorders and Neurogenic Bladder, Jacobs Neurologic
Institute, Buffalo General Hospital, Buffalo, NY; Instructor of
Urology, New York Osteopathic Medicine, New York, NY;
Instructor of Urology Lake Erie College of Osteopathic
Medicine, Erie, PA

### Michael A. Altman, MD

Associate Professor, Department of Family and Community Medicine, University of Texas Medical School at Houston, Houston, TX

### Gerald A. Amundsen, MD

Faculty, Great Plains Family Medicine Residency, Oklahoma City; Physician, Mustang Family Practice, Mustang, OK

### John J. Andazola, MD

Program Director, The Southern New Mexico Family Medicine Residency Program, Las Cruces, NM

### Fatih Arikan, DDS, PhD

Associate Professor, Department of Periodontology, Ege University School of Dentistry, Bornova, Izmir, Turkey

### K.M.R. Arnold, MD

Assistant Clinical Professor, Department of Family Medicine, University of Indiana, Indianapolis, IN

### Darrin Ashbrooks, MD

Department of Family Medicine, University of Arkansas for Medical Science AHEC–Southwest, Texarkana, AR; Department of Sports Medicine, University of Kansas City– Missouri School of Medicine, Kansas City, MO

### **Barry Auster, MD**

Clinical Instuctor of Dermatology, Michigan State University, East Lansing; Chair of Dermatology, Sinai-Grace, Detroit; Department of Dermatology, William Beaumont Hospital, Royal Oak, MI

### Dennis E. Babel, PhD, HCLD (ABB)

Laboratory Director, Mycology Consultants Laboratory, Holland, MI

### Thad J. Barkdull, MD, FAAFP, CAQSM

Clinical Assistant Professor, Department of Family Medicine, John A. Burns School of Medicine, University of Hawaii; Director of Sports Medicine, Family Medicine Residency, Tripler Army Medical Center, Honolulu, HI

### Andy S. Barnett, MD

Clinical Instructor, Department of Family Medicine, University of Washington and Madigan Army Medical Center, Tacoma; Staff Physician, Department of Emergency Medicine, Jefferson General Hospital, Port Townsend, WA

### Rebecca Beach, MD

Residency Faculty, Mercy Health System Family Medicine Residency; Family Physician, Mercy Clinic South, Janesville, WI; Clinical Assistant Professor, University of Wisconsin– Madison, Madison, WI

### Jennifer Bell, MD

Clinical Instructor, Departments of Family and Preventive Medicine, University of Utah, Salt Lake City, UT

### J. Michael Berry, MD

Associate Clinical Professor of Medicine, Division of Hematology–Oncology, University of California–San Francisco; Associate Director of HPV–Related Clinical Studies, UCSF Helen Diller Family Comprehensive Cancer Center, San Francisco, CA

### Christopher J. Bigelow, MD

Ophthalmologist, MidMichigan Medical Center, Midland, MI

### Lee I. Blecher, MD

Assistant Clinical Professor of Family Medicine, Virginia Commonwealth University School of Medicine; Fairfax Family Medicine, Fairfax, VA

### David T. Bortel, MD, ABOS

Staff Orthopedic Surgeon–Joint Replacements, MidMichigan Medical Center, Midland, MI

### David B. Bosscher, DO, FAAFP

Staff, Allegan General Hospital, Allegan, MI

### Jamie Broomfield, MD

Associate Professor, University of Wyoming Family Medicine Residency Program at Cheyenne, Cheyenne, WY

Clinical Professor, The Commonwealth Medical College, Scranton; Clinical Associate Professor, Temple University, Philadelphia; Medical Director, Procter & Gamble Paper Products, Mehoophany, PA The face of medicine has changed drastically since the first edition of this text was published in 1994. The intervening 16 years have seen a revolution in computers and technology. New procedures have been introduced. Electronic medical records are being rapidly adopted. The government has just passed a new healthcare reform bill. Medicine has become more regulated and much more of a business. The vision of the family physician "who can provide a breadth and continuity of commonly needed healthcare services for adults and children; who can deliver babies, manage simple fractures, counsel single parents, go to the hospital, maintain an office, and, when all else fails, comfort the dying; ... who provides healthcare from the nursery to the nursing home, without taking the patient to the poorhouse along the way," as defined by Dr. Rodney in the forward to the first edition, becomes more elusive.\*

This indeed is a time of change. Rapid change. Warp speed change. A time of excitement and confusion. A time of bewilderment and futuristic goals. A time for huge potential growth.

The primary care clinician stands at the threshold of this change. Measuring quality has been implemented. The Family Medical Home has been introduced and is being incorporated into routine care by many. It is now the focus of hope to manage healthcare delivery in the future.

In all this change and turmoil, we must be careful to recall that the care of the patient remains the primary goal of the medical system. The goal is not to meet some time constraint for an office visit or hospital stay, or to follow some protocol or clinical guideline, or to meet the budget. Rather, the goal of our care is the health of our patients and their families. That goal gives us our purpose and is the reason we became physicians, clinicians, and healers.

Having primary care providers perform procedures still makes sense in the new order of healthcare. It can be a part of the proposed Family Medical Home. Many of these procedures can be performed in the office, which reduces cost. They can be offered by clinicians who know their patients, which the patients appreciate. Performing procedures in the office reduces the time needed to complete referrals to other specialists and reduces delay in the diagnosis and treatment of many conditions. It also makes it easier to document that necessary procedures were actually performed and that patients were not lost in the system. If healthcare reimbursement becomes more "bundled," it will make sense for the primary care clinician to provide even more procedural care. Performing procedures is also rewarding for practitioners and can enhance their enjoyment of the practice of medicine. That said, the quality of the procedures performed can and must meet or surpass the highest of standards. This text helps meet that goal.

We appreciate the feedback we have received on the first two editions. New features in this edition include colored photos and two complete new sections: Aesthetic Medicine and Hospitalist Procedures. Adding these sections reflects some of the changes in medicine. The patient's desire to look younger and healthier has been coupled with advancements in technology to accomplish just that. Hospitalist care has become the norm and is more focused and complicated; yet the associated procedures are not out of the range of primary care clinicians. Family physicians and other primary care clinicians, because of their breadth and depth of training, can step up to these new areas of healthcare and bring these procedures to their patients.

Times change. The experts, academics, and politicians move on. New technology and procedures are invented. But the need for that healer and caregiver who really does care will never change. The fear and trepidation that a patient often experiences can only be alleviated by the touch, the words, and the expertise of the caring clinician. In our search for the knowledge and expertise to perform the procedures presented in this text, we should never forget that, first and foremost, we are people who treat patients and their families, not just their symptoms. We learn and gain the skills to perform the procedures reviewed in this text to aid healing. Procedures are not goals unto themselves; rather, they are included in our expertise as another way to help people feel better and be healther.

John L. Pfenninger, MD Grant C. Fowler, MD

<sup>\*</sup>Pfenninger JL, Fowler GC: Procedures for Primary Care Physicians. Mosby, 1994.

### PREFACE TO THE FIRST EDITION

The inspiration for this text came from busy primary care physicians across the country. Medicine in the 1990s is changing rapidly. The high cost of hospital care, emergency room visits, and even the expenses of freestanding day surgery centers have created a forceful impetus for physicians to perform previous hospital-based procedures and surgeries in the office. Fast-paced lifestyles have added performance pressure: the patient's time is at a premium. No longer will they accept referrals for simple procedures or the subsequent inconvenience. Patients expect their physician to perform most routine procedures. In certain areas of the country, competition for patients has increased, resulting in the need for physicians to master certain procedural skills to enhance their status and desirability. Overwhelmed with paperwork and other responsibilities, primary care physicians have little time to spend preparing for or performing a procedure (much less orienting their staff), and yet some procedures in the office are becoming more complex. Thus, among other things, physicians are pressured from patients, healthcare plans, greater competition, paperwork, and their own staff. It was at the urge and cry of these pressured physicians for a concise, and yet allencompassing, reference for procedures that this book was created.

Coupled with these pressures, there has been a parallel explosion in new technology. There has also been a clarification and refinement in techniques and indications for older technology. Safer medications and monitoring units are also available to facilitate performing procedures in the office. However, few primary care physicians have the time to stay up-to-date with the changes in technology. New technology or new applications of old technology allow definitive care for conditions in a simpler fashion with less risk and expense than ever before. Radio-frequency loop cervical conization, which is now done in the office setting, has, or will soon, replace the majority of in-hospital cervical conizations. This procedure may cost as little as 20% of in-hospital costs. Fiberoptic diagnoses allow for a more comprehensive evaluation and earlier diagnosis of cancer. More importantly, these diagnoses can now be made by the same physician who cares for the patient most of the time. These technological advances save lives, add to the quality of life, are cost effective, and decrease liability.

Interestingly, there is a wide variety of procedures currently being performed by primary care physicians. However, there are large individual and geographic variations. These variations will no doubt diminish with the advent of managed care. It is well known that it is very cost effective to keep procedures in the hands of primary care physicians, yet there is no comprehensive text detailing the performance of these procedures. With our first attempt, this text is not yet perfect. We relied on authors from all over the country and more than 80 authors contributed. There is a wide range of style and practicality. The intent of the text is to give direction and to serve as a resource and brief review for a particular procedure—not to be all-inclusive in a single text.

The chapters in this book in no way intend to make the reader an expert at any procedure. It is a rare procedure that can be safely "learned from the book." The majority of procedures will be mastered by attending courses that are then followed by a preceptor arrangement. The text merely combines and lists those procedures that primary care physicians perform, sometimes on a daily basis. The text may also serve as a review for physicians and staff on those procedures that are not performed on a day-to-day basis.

Procedures for Primary Care Physicians is not a static document. It will grow and change with time. The chapters will be refined and the contents revised to be more concise and direct. This can only happen through feedback from the readers. Suggestions from you, the reader, would be most appreciated. Submissions of new, or even alternatives, to current chapters are most welcome.

As the title states, this text is directed to primary care physicians—family and general practitioners, emergency physicians, pediatricians, obstetricians, internists, house officers, medical students, military medics, paramedics, nurse practitioners, and all other "primary care providers." It is hoped that the contents will enhance the performance of procedures, improve patient care and satisfaction, and lead to greater physician self-fulfillment.

John L. Pfenninger, MD Grant C. Fowler, MD

### **ACKNOWLEDGMENTS**

We would like to give special thanks to Julie Mirra at Elsevier for persisting with us through this edition. Despite an incredible number of necessary communications to authors and editors, she kept us on track. Without her steadfast and unwavering support, we might still be working on this project!

We would also like to acknowledge the support of Rolla Couchman, with his good humor, Druanne Martin with her continuous, nurturing support, and Kate Dimock, our final connection at Elsevier. Delores Meloni also assisted us. Thanks to Adrianne Brigido who helped us get the project going and to others at Elsevier who also helped.

Nancy Lombardi did a tremendous job. Her attention to detail was amazing as she even corrected some errors that were present

in the first and second editions. Her expertise was very much appreciated.

Thanks from Jack Pfenninger to the MidMichigan Medical Center medical librarians, Pat Wolfgram and Jill VanBuskirk, for their help in researching references, and to Kay Pfenninger for her many hours of scanning slides and overall editing support. Thanks, too, to my office staff who accepted all of my excuses for not completing office tasks on time while I worked on the book! They include Maggie Maurer, Linda Headley, Mary Dansa, Annette Reihl, June Waterman, Peggy Wisneski, and Deana Hegyi.

Grant Fowler would also like to acknowledge Margaret Zambrano and Carolyn Love for their outstanding administrative support of this and similar projects over the years.

### **ACKNOWLEDGMENTS TO THE FIRST EDITION**

The number of people to be thanked in a text of this magnitude is too great to allow mention of them all. Each, in his or her own way, has added greatly to its value. The special people who provided their support and encouragement include: Grant Fowler, MD, for giving large blocks of his time and expertise—without his assistance, the text would be nowhere near completion; Len Scarpinato, DO, for his editorial assistance; Barbara Apgar, MD, for the moral support needed when the "going got rough;" Don DeWitt, MD, for encouraging the vision; Pat Wolfgram, the hospital librarian, for retrieving the voluminous number of reference articles; Joan Haddix, Joi Henton, and Shirley Marsh, for their typing assistance; and Beth Moe, Denise Willard, and Linda Hallman for their secretarial skills. To Ted Huff, I give my sincere thanks for developing educational diagrams out of what were sometimes mere scratchings of the pen. A sincere thanks goes to Cindy Trickel of Carlisle Publishers Services, who provided invaluable editorial guidance in converting thoughts into words.

A special thanks also goes to all the family physicians in Midland, Michigan. They not only provided after-hours coverage for me, but also provided the encouragement to continue on through

many personal crises. My office staff and nurses also deserve my gratitude.

Each and every author of this book also deserves special recognition. There were many refusals to assist in this project because of over-commitment and lack of belief in the project. For those authors who did contribute, it meant extra sacrifice and dedication. They participated in a dream that has now come to fruition.

To all of these, a sincere thank you.

### John L. Pfenninger, MD

A special thanks to the residents, faculty, and staff of the Hermann/LBJ Family Practice Program and the Department of Family Practice and Community Medicine at the University of Texas Houston Health Science Center–Medical School for their contributions, patience, and encouragement—without which this book might not have happened.

Grant C. Fowler, MD

There are two sides to the complete primary care physician. One side is the compassionate listener, a person who can heal with words. The other side is the talented caregiver who can provide and apply medical science, including necessary or desired procedures for patients. People need people for good health, and those who have a complete primary care physician who knows them and treats them are among the luckiest people in the world. The complete primary care physician is a precious resource that has been endangered but is making a comeback.

Pfenninger and Fowler's *Procedures for Primary Care* is the bible for the laying on of hands in primary care practice. The first edition in 1994 sold over 40,000 copies and became a fixture in the library of every residency program. It is the one book that is worn and well-used. The second edition in 2003 had 82 new chapters and cemented the book as a must-have in every primary care office. The third edition expands this classic text to an amazing 234 chapters with two new sections, Aesthetic Medicine and Hospitalist Procedures.

The scope of primary care is expanding. After years of decline because of "turf wars" with specialists, health systems are appreciating more than ever that having multitalented primary care physicians is the key to efficient and high-quality healthcare delivery. Comprehensiveness is now back in style for primary care with the Patient-Centered Medical Home as the provider and coordinator of all healthcare services. This is not the "gatekeeping" of managed care but rather a "place" where patients share an information system with their personal physician and have all their services coordinated. The more the primary care physician team can do, the better for everyone.

I am fortunate to be "walking the talk" of the Patient-Centered Medical Home model. In 2009, I was asked to develop a new primary care practice network in a heavily doctored area of southern California. Building off the practice of one physician, we will have 9 offices and 26 physicians in early 2011. We are starting residency programs in family medicine and internal medicine. All practices qualify as advanced medical homes. We have established a variety of "procedure clinics" among our group, performing a wide variety of dermatologic procedures and aesthetics. We have expertise among us in sports medicine. We are developing our own hospitalist service. While no primary care physician will do all the procedures described in this book, among us we will do almost all of them. We will train a new generation of primary care physicians in as many procedures as time and interest allows. *Procedures for Primary Care* is our indispensable guide.

There is a renaissance underway in primary care. The internet and information technology change how we do most everything, and primary care is no exception. Patients now have access to a world of information for free, including healthcare and their medical records. Primary care physicians have become "information managers" for patients and access to communication online has become continuous. In this new world of information, communication, and continuous care, what patients need and want is shared decision making. For patients, an "I can do that for you" from their primary care physician is usually a welcome relief. The world of specialists is often confusing and usually very expensive. Good primary care exudes value, the combination of quality and efficiency, so needed and welcomed in healthcare today.

Knowledge is power and knowledge is abundantly available in *Procedures for Primary Care*. Jack Pfenninger and Grant Fowler have assembled a phenomenal group of talented authors who all "walk the talk" of their chapters. Need to remove a fishhook? Need to remove a ring from a swollen finger? Remove isolated hairs for good? Apply an Unna boot? Repair an earlobe? This book has procedures for them all, of course, and these examples are only a small slice of what is here. If you want to venture into Botox treatment or provide stress echocardiograms, this book will tell you how. We often go to workshops to learn new procedures, but what is helpful to keep doing them is a handy reference to remind us of all the elements of the procedure.

Patient safety requires that we have a checklist for each procedure and not just rely on what we and our staff remember at the time. This book has all the checklists. I imagine a thousand times a day physicians and office staffs somewhere are reviewing a chapter in this book before going into the treatment room. Copies of these checklists should become part of your office procedure manual.

I am certain that this will not be the last edition of *Procedures* for *Primary Care*. This resource is simply too valuable not to have, and access to it needs to be in print in every office. With this edition, the patient education sheets have been moved online to make downloading and printing easier and more convenient. I imagine synergy with the internet will grow over time as it has with other classic textbooks. For now, having a readily available copy of *Procedures for Primary Care* will be at the top of your office resources. Use it often to keep your quality of care high and your scope of practice broad for the benefit of your patients.

### Joseph E. Scherger, MD, MPH

Vice President, Primary Care Eisenhower Medical Center Rancho Mirage, CA Clinical Professor of Family Medicine University of California, San Diego University of Southern California

### **FOREWORD TO THE SECOND EDITION**

As a comprehensive guide to performing medical and surgical procedures in the office, hospital, or emergency department, *Pfenninger and Fowler's Procedures for Primary Care* might be considered an antidote to the evils that originated from Pandora's box. According to Greek mythology, Pandora (whose name means "rich in gifts") found a buried box and impulsively removed its lid. Out of the box, scattering in every direction, came disease, death, and all the other evils that afflict humankind. Like Eve in the Christian scriptures, Pandora introduced mortality into our world. However, her box also contained an antidote—hope—and she closed the lid just in time to prevent this quality from escaping.

In combating the myriad diseases that Pandora supposedly unleashed, primary care clinicians have long been powerful agents for hope and healing. Because of advances in treatment options, including minimally invasive outpatient surgical techniques, many procedures that previously would have necessitated hospitalization or consultation now can be performed by primary care clinicians in the office, hospital, or emergency room. This arrangement allows continuity of care, hopefully provides excellent patient education, and, by moving some procedures out of the hospital, may offer significant economic advantages. However, as their role expands, these clinicians must continue to use sound judgment and keep the patient's welfare as the uppermost priority. They should avoid procedures beyond their expertise; they should avoid procedures that might necessitate repetition; and they should avoid procedures that might cause them medicolegal problems.

Like Pandora, *Pfenninger and Fowler's Procedures for Primary Care* is rich in gifts, but these are of the life-affirming kind. More than 200 chapters provide up-to-date information for a continually evolving specialty. The book includes practical, step-by-step instructions for performing an extensive array of medical and surgical procedures, as illustrated by line drawings and clear photographs. It also covers indications and contraindications, equipment and suppliers, complications, billing codes, and other practical topics. In the literature for primary care clinicians, few other books cover such a wide range of topics. Indeed, I know of no other volume that is likely to be more useful to its intended audience.

Some readers may wonder why this foreword is being written by a cardiovascular surgeon and not by a primary care clinician. Perhaps

they will allow heart disease to serve as an example for many other diseases. Primary care clinicians are at the leading edge of the battle against many diseases—not only in treatment but also in prevention. Regarding heart disease, their advice is often the deciding factor in convincing patients to make positive changes with respect to fat intake, physical activity, cigarette smoking, and other lifestyle factors. An example from the recent literature supports this premise: in a study involving patients with coronary artery disease at Creighton University, recommendations from primary care clinicians concerning the assessment of lipid profiles and use of statin therapy significantly reduced the number of adverse cardiovascular outcomes. As the average age of the population continues to increase and congestive heart failure becomes increasingly prevalent, primary care clinicians can be expected to play an even greater role in diagnosing and treating this disorder. If primary care clinicians can do this with heart disease, it is my hope that they can use their abilities in many other areas of medicine.

The book also contains patient education handouts. When primary care clinicians perform a procedure, they must know the disease well. In so doing, they also have a golden opportunity to teach some prevention principles. I hope that they will never miss the opportunity to treat the whole patient and potentially change the course of the disease by educating the patient before, during, and after performing the procedure.

In conclusion, I congratulate Drs. Pfenninger and Fowler on producing such an excellent volume. It should help improve the quality of care in many aspects of medical practice, and I highly recommend it for every primary care clinician and trainee. There are some who consider me a pioneer in heart disease; I hope that this book encourages medical pioneers everywhere to prevent and treat early the diseases that Pandora supposedly released.

Denton A. Cooley, MD

Surgeon-in-Chief, Texas Heart Institute Clinical Professor of Surgery University of Texas Medical School at Houston Houston, TX

### FOREWORD TO THE FIRST EDITION

In 1930, more than 80% of the physicians in the United States were general family doctors, providing comprehensive health care at a reasonable cost. By 1980, the self-reported percentage of family doctors in the United States was 15%. Along with this trend of dwindling numbers has been a gradual decline of diagnostic and therapeutic skills held by those physicians who do practice general family medicine.

One definition of a generalist physician (formerly a general practitioner) is a family physician who can provide a breadth and continuity of commonly needed healthcare services. These physicians care for children, deliver babies, manage simple fractures, counsel single parents, go to the hospital, maintain an office, and, when all else fails, comfort the dying. Their goal is to provide health care from the nursery to the nursing home, without taking the patient to the poor house along the way

Today, of the 625,000 physicians in the United States, fewer than 10% comprehensively wield the clinical skills needed to provide such care. The headlong rush to subspecialize in medicine has left family physicians in the minority. Still, they are an important minority whose number is now growing in response to the projected needs of the twenty-first century American healthcare system.

Since 1983, a group of family physicians, supported by the American Academy of Family Physicians (AAFP), has constructed a series of demonstration projects to propagate diagnostic and therapeutic skills in family medicine. Many of the procedural pioneers in family practice have quietly and unselfishly contributed their professional energies to the resuscitation of full-service family practice within a medical education system gone far, far astray. This book stands as a contribution to that effort. Although some may view the teaching and learning of clinical skills as "proceduralism," the skills that are depicted in this book represent the desire of physicians to remain clinically excellent. No amount of psychosocial expertise can overcome the credibility lost when a physician cannot perform basic clinical services on behalf of his or her patient.

Recently a prominent dean of a well-known medical school asked me why the residency programs at my institution, the University of Tennessee, persisted in reaching a comprehensive set of procedural clinical skills when, in his opinion, managed care

organizations and health maintenance organizations would effectively amputate these skills from the day-to-day practice of family physicians. I disagree with this vision of the future, but it is true that some family physicians voluntarily relinquish many of the clinical skills described in this book. It is my hope that the skills described in its pages will become required curriculum, not only for residents, but, particularly, for faculty. One of the major challenges for the success of this book (and the specialty of family practice) is the development of accountability in a healthcare system that has become overly fragmented, costly, and inaccessible.

Are these skills needed? During the past 20 years, family physicians have been manipulated, exploited, and oppressed in a variety of ways that makes study of their actual needs very complex. For example, a lack of reported interest in obstetrical care cannot be used to justify the tremendous void that exists in women's health-care as provided by family physicians. Residents are not likely to acquire clinical skills that family physician faculty members cannot themselves demonstrate in their positions as role models. A lack of procedural skill among family practice faculty and practitioners is particularly troubling in rural and underserved communities. These communities cannot afford platoons of various subspecialized physicians.

Although excellent healthcare is available from a combination of obstetricians, pediatricians, and internists, a well-trained, comprehensive-care family physician should be able to deliver continuing healthcare unrestricted by age, sex, organ system, and pregnancy. The physician should be skilled in many of the procedures described here to screen for, prevent, and treat common disease entities. If family practice simply becomes synonymous with "generic primary care," there will be very little need for many of the skills described in this book. My compliments to the editors and the authors for executing a labor of love in an outstanding fashion. They have chosen the road less traveled.

### Wm. MacMillian Rodney, MD, FAAFP, FACEP

Meharry/Vanderbilt Professor and Chair Department of Family and Community Medicine Professor Surgery/Emergency Medicine Meharry Medical College Nashville, TN

### BIER BLOCK

Peter W. Grigg

Intravenous (IV) regional anesthesia, also known as a *Bier block*, is a useful method of providing operative anesthesia to wide areas of the distal portion of an extremity. When executed with proper technique, the Bier block is a safe alternative to local or hematoma infiltration, and provides anesthesia superior to these other methods. At the same time, it has the advantage of being technically simpler to perform than other regional alternatives (e.g., axillary or brachial plexus block).

### **INDICATIONS**

Although the technique of IV regional anesthesia has been used on the lower extremity, it is most often used in applications involving the upper extremity. Bier blocks are useful for (1) surgery of the wrist, hand, and fingers (e.g., carpal tunnel release, foreign body removal, laceration repair, incision and drainage, and tendon release and repair); and (2) reduction of fractures or dislocation below the elbow. Bier blocks are also used in the treatment of complex regional pain syndromes.

### **CONTRAINDICATIONS**

Documented sensitivity to local anesthesia is an absolute contraindication. Relative contraindications include the following:

- Injuries to the proximal extremity that would be adversely affected by application of a tourniquet (e.g., crush injury)
- Conditions predisposing to arterial thrombosis (e.g., Raynaud's phenomenon, homozygous sickle cell disease)
- Fractures about and above the elbow
- Infection at or near the intended IV cannula insertion site
- Preexisting cardiac disorders affected by IV local anesthetic (e.g., untreated third-degree heart block)
- Difficulty in maintaining arterial occlusion with a tourniquet (e.g., inadequate cuff size in a massively obese patient)

### **EQUIPMENT**

- Standard monitoring equipment (cardiac monitor, pulse oximeter, continuous blood pressure monitor)
- Standard Advanced Cardiac Life Support (ACLS) airway supplies and drugs, as well as drugs used for sedation (e.g., midazolam [Versed], fentanyl, and propofol [Diprivan])
- Double-cuff automatic pneumatic tourniquet that can individually or simultaneously inflate or deflate both cuffs to preset pressures (as an alternative, ordinary blood pressure cuffs can be used if the dimensions of the arm can accommodate two appropriately sized cuffs between the axilla and the elbow without overlap)
- Lidocaine (without epinephrine), 1 mL/kg of 0.5% solution for upper extremity blocks, 2 mL/kg of the 0.25% solution for lower extremity blocks
- Two IV catheters, a 22-gauge line for the operative side and a 20-gauge line for the arm on the nonoperative side, which can

be used for sedation and administration of emergency drugs if needed

- Sterile skin preparation solution (e.g., povidone-iodine)
- Tape
- Elastic bandage of sufficient size to wrap the entire extremity distal to the tourniquet

Although the risk of serious adverse reaction is very small when the procedure is followed correctly, it should be conducted only in facilities capable of managing serious local anesthetic toxicities (see the Complications section, later).

American Society of Anesthesiologists standards require an anesthesiologist (or a similarly qualified practitioner other than the surgeon) to manage the patient during a Bier block. This person should not be the operating surgeon because the surgeon is busy doing the procedure and cannot effectively manage complications of the local anesthetic.

### PREPROCEDURE PATIENT PREPARATION

Advise the patient that 95% of patients experience good or complete anesthesia with a Bier block; the remainder require additional analgesics or sedatives. Explain the risks, alternatives, and potential complications to the patient and answer any questions. Note that anesthesia will resolve in 30 minutes or less after tourniquet release. See patient education and patient consent forms available online.

### **TECHNIQUE**

- 1. Perform a focused history and physical examination to ensure the patient is a candidate for a Bier block. Note NPO status, medical problems, medication allergies, and Mallampati airway classification (see Chapter 2, Procedural Sedation and Analgesia).
- Attach the cardiac monitor and pulse oximeter. Place the blood pressure cuff on the nonoperative side and note the patient's blood pressure.
- 3. Place two IV lines—one on the operative side, and one on the nonoperative side. On the operative side, attach the syringe with lidocaine and tape in place.
- 4. An ACLS-trained practitioner should administer the sedation and monitor the patient as previously noted. An IV tranquilizer such as midazolam (Versed) 2 to 4 mg IV often is given for comfort, although sedation is not required.
- 5. Test the pneumatic tourniquet or blood pressure cuffs for accuracy and maintenance of pressure and then place them on the proximal portion of the extremity.
- 6. Have an assistant elevate the extremity above the heart while you wrap the elastic bandage around it, wrapping from distal to proximal (from fingers or toes up to the distal cuff). Be careful not to dislodge the needle or catheter.
- 7. Rapidly inflate the proximal cuff to 50 to 100 mm Hg above the systolic blood pressure for upper extremity blocks and twice the

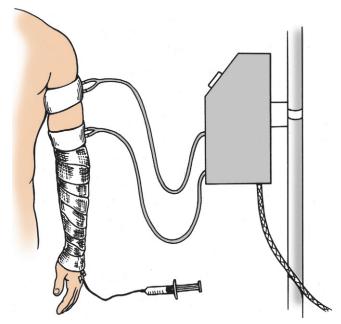

Figure 1-1 Bier block procedure, before removal of elastic bandage and injection of lidocaine, showing inflation of proximal cuff.

- systolic blood pressure for lower extremity blocks. Assign an assistant to be responsible for continuously monitoring the maintenance of cuff pressure throughout the remainder of the procedure (Fig. 1-1).
- 8. Lower the extremity, remove the elastic bandage, and check the distal pulses. If no pulse is palpable and the extremity is blanched, inject the appropriate dose of lidocaine.
- 9. After approximately 10 to 15 minutes, check the adequacy of anesthesia by gently manipulating the operative site. Additional time may be required to achieve full effect.
- 10. After the initial 10 to 15 minutes, inflate the distal cuff to the same pressure as the proximal cuff, and then deflate the proximal cuff. This use of two cuffs reduces the pain associated with the occlusive tourniquet by allowing infusion of the anesthetic under the proximal cuff before it is inflated.
- 11. When anesthesia is deemed adequate, the IV line on the operative side may be removed. The limb is then prepared, and the operation may proceed up to a maximum inflation time of 2 hours. Periodically monitor the blood pressure on the contralateral side to ensure proper tourniquet pressure. The tourniquet may remain inflated during the process of taking intraoperative plain films.
- 12. At the completion of the procedure, but no sooner than 20 minutes after lidocaine injection (to permit diffusion of some of the lidocaine out of the vascular system), deflate and remove the cuffs. Some physicians recommend cycles of deflation and inflation, but this has no advantage in lowering systemic plasma lidocaine levels.
- Observe the patient for 10 to 15 minutes for signs of toxicity or adverse reaction.

### **COMPLICATIONS**

See Chapter 5, Local and Topical Anesthetic Complications.

 Complications arise from the lidocaine and the equipment used to produce the block. Minor adverse reactions to the lidocaine (e.g., dizziness, tinnitus, bradycardia) occur in fewer than 2% of patients after cuff deflation.

- Allergic reactions are very rare. Anaphylaxis is treated with oxygen therapy, IV fluid, epinephrine, antihistamines, and steroids.
- Seizures and cardiovascular collapse occur almost exclusively when the lidocaine is injected with the cuffs deflated—because of operator error or equipment malfunction—and are rare. Seizures may be self-limited and treated with airway management, IV benzodiazepines, barbiturates, or propofol.
- Dysrhythmias are treated according to ACLS algorithms.
- Hypotension may require IV fluids or vasopressors.
- Ecchymosis and subcutaneous hemorrhage can occur underneath the cuff site and can be minimized by placing padding (web roll) on the arm.
- Engorgement of the extremity can occur when arterial inflow of blood continues but venous drainage is restricted by the tourniquet. A fully functional tourniquet and checking for an absent pulse minimize this problem.
- Hematoma formation can occur at sites of unsuccessful IV attempts. Apply pressure for 3 minutes before applying elastic bandage. Apply pressure over the IV site when the functioning catheter is removed.

### PROCEDURAL SEDATION AND ANALGESIA

Sylvana Guidotti

Procedural sedation and analgesia (PSA) is the clinical practice of using pharmacologic agents to achieve a measurable level of sedation, while performing typically painful or anxiety-provoking procedures. The term *conscious sedation* is no longer used because it describes neither the intent nor the outcome of the process. PSA allows the nonanesthesiologist to perform selected procedures in a safe and controlled setting.

The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) has produced sedation guidelines to describe and define the spectrum of PSA. More important, the American Society of Anesthesiologists (ASA) and the American College of Emergency Physicians (ACEP) have published guidelines for PSA by nonanesthesiologists and emergency physicians, respectively. As defined by the ASA, PSA is a continuum from minimal sedation/analgesia to general anesthesia.

Minimal sedation occurs when the patient continues to respond normally to verbal commands without cardiopulmonary functions being affected. Moderate sedation is a state of depressed consciousness where the patient responds appropriately to verbal command with or without light tactile stimuli. Dissociative sedation should be considered a form of moderate sedation that occurs when a dissociative pharmacologic agent produces a trancelike state. The result is analgesia and amnesia while protective airway reflexes and cardiovascular stability are maintained. Deep sedation causes a depression of consciousness in which the patient is not easily arousable but responds purposefully with repeated or painful stimuli. At this level, the patient may require assistance in maintaining airway and ventilation. General anesthesia is at the end of the spectrum; consciousness is lost and the patient is unarousable to any stimuli. The patient requires ventilatory assistance, and cardiovascular function may be affected or impaired.

For coding purposes, the American Medical Association CPT coding manual describes "moderate (conscious) sedation" as a druginduced depression of consciousness during which patients respond purposefully to verbal commands, either alone or accompanied by light tactile stimulation. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is maintained. It does not include minimal sedation (anxiolysis), deep sedation, or monitored anesthesia care (Table 2-1).

PSA comprises three components. First there is the *process of sedation*, which requires a thorough knowledge of the agents being administered. Next is the *intended procedure* to be performed. Finally, there are the *unpredictable side effects and untoward reactions* to the sedating medications, which can occur during or in the recovery phase of the procedure.

The physician should be familiar with all of the appropriate monitoring and rescue equipment. A suitably trained provider should assist with the sedation. All individuals who participate in

the care of the patient undergoing PSA must demonstrate ongoing clinical competency and be privileged for the procedure if they will be performing it in a hospital setting.

### **INDICATIONS**

As nonanesthesiologist physicians become more comfortable with PSA, the roster of appropriate procedures where these agents are beneficial continues to expand. The list includes, but is not limited to, the following:

- Anal procedures
- Biopsy procedures
- Bone marrow aspiration or biopsy
- Bronchoscopy
- Cardioversion (electrical or chemical)
- Dental/oral surgical procedures
- Endometrial biopsy
- Essure contraceptive placement
- Fracture reductions/care
- Gastrointestinal endoscopy
- Hysterosalpingography
- Lumbar puncture
- Magnetic resonance imaging/computed tomography scans/invasive radiographic procedures
- Office dilation and curettage/vacuum aspiration
- Orthopedic procedures
- Phlebectomy
- Plastic/cosmetic/laser procedures
- Wound repair/care, including burns; large excisions

PSA can be used in conjunction with and as a supplement to digital blocks, hematoma blocks, or regional nerve blocks as well as topical anesthetic agents. These modalities may obviate the need for deeper levels of sedation. Other distractions for the patient such as music or videos are useful adjuncts.

### **CONTRAINDICATIONS**

Elective procedures on pregnant patients should be deferred until after delivery. Patients with severe unstable systemic disease and patients with potentially unstable airways should be directed to a higher level of care. The ASA classification of systemic disease is designed to guide the physician as to which patients are appropriate candidates for PSA (Table 2-2).

Class II patients include those with well-controlled hypertension, controlled non-insulin-dependent diabetes, and minimal cardiac or respiratory disease. Class III patients include those with insulin-dependent diabetes mellitus, poorly controlled hypertension, significant cardiac or respiratory disease, and significant renal

Operational Definitions and Characterizations of Levels of Sedation-Analgesia TABLE 2-I Response **Sedation** Level of Ventilation, **Verbal Level of Consciousness Tactile S**core **Sedation Patency** Oxygenation Р Р Р Р 0 None Fully aware of self and surroundings P-L "Minimal" Mostly aware of self and surroundings, but sedate Ρ 2 P-L P\_I : P\_I \* "Moderate" Slightly aware of self and surroundings, usually somnolent, L-A arouses easily with stimuli 3 "Deep" L (to pain) Not aware of self or surroundings, little arousal with stimuli Α L-A 4 General anesthesia Unconscious, no arousal with painful stimuli A (to pain) L-A

A, absent, inadequate; L, limited, partial, mildly abnormal; P, present, adequate, or normal.

or hepatic disease. Based on individual experience and skill in providing sedation, practitioners may decide to limit the amount of patient risk they are willing to accept, using the ASA guidelines.

In general, the nonanesthesiologist physician who provides PSA in the private office setting should do so on patients with class II status or less. For hospital-based procedures outside of the operating room, PSA may be performed on patients up to and including class III status.

The ASA has set forth *preprocedure fasting guidelines* for scheduled elective cases. However, in separate recommendations for PSA, the ASA states, "The literature does not provide sufficient evidence to test the hypothesis that preprocedure fasting results in a decreased incidence of adverse outcomes in patients undergoing either moderate or deep sedation." The current guidelines are the result of consensus, rather than being evidence based, with respect to the risk of aspiration. *The recommendations are 6 hours for solids, cow's milk, and infant formula; 4 hours for breast milk; and 2 hours for clear liquids.* ACEP recognizes that there are certain emergent situations in which the benefits of PSA at any sedation depth outweigh the potential risks. In all other circumstances, it would be best to strictly adhere to the fasting guidelines. Thus, if a patient has not followed the aforementioned fasting guidelines, it would be best to postpone the procedure or just not use significant PSA.

### **EQUIPMENT**

- A single unit with blood pressure and electrocardiographic measurements, variable-pitch beep pulse oximeter, and recording device is the ideal monitor for PSA. Individual units are acceptable but require repeated manual recordings of the readings on the patient's chart.
- Angiocatheter for intravenous (IV) access (at least 20 gauge), IV solution, and stand.
- Oxygen source.
- Medications for sedation and analgesia.
- Reversal medications.

- Diphenhydramine and epinephrine to be used in the event of severe allergic reactions.
- Crash cart or Banyan kit with equipment and medications for basic and advanced cardiac life support (ACLS; see Chapter 220, Anaphylaxis).
- Suction device.
- Defibrillator (Fig. 2-1).

Although it is not a requirement for class I patients, the *application of oxygen* by nasal cannula should be used for every patient undergoing PSA because each patient has a unique and unpredictable response to the medications. *Capnometry* is another, more sensitive measurement of ventilatory status and is being used as part of PSA monitoring. As a measure of exhaled carbon dioxide, end-tidal  $CO_2$  may detect hypoventilation before the development of oxygen desaturation.

### **PERSONNEL**

At least two providers must be involved in PSA. The physician who is performing the procedure is also ordering the medications. The assistant is typically a registered nurse who has fulfilled all of the requirements to administer PSA drugs, monitor the patient during the procedure and recovery phase, and participate in any needed resuscitations.

There should be a well-defined response for any cardiopulmonary emergency that results from PSA. Most hospitals have organized a "code team" to respond to such situations. In the nonhospital setting, the physician should be able to manage the emergency until emergency medical services personnel arrive for transport to a hospital.

### PREPROCEDURE PATIENT ASSESSMENT

Every patient who undergoes PSA should have a complete history and physical examination before the procedure. Included in the

(ASA) Physical Status Classification	TABLE 2-2	American :	Society of Anesthesiologists
	(ASA) Phy	sical Status (	Classification

· / /	
ASA Classification	Sedation Risk
Class I: Normal healthy patient Class II: Mild systemic disease without physical limitation	Minimal Low
Class III: Severe systemic disease with functional limitations	Intermediate
Class IV: Severe systemic disease that is a constant threat to life	High
Class V: Moribund patient who may not survive without procedure	Extremely high

**Figure 2-1 Defibrillator.** (Courtesy of Zoll Medical Corp., Chelmsford, Mass.)

<sup>\*</sup>May need to supplement oxygen to maintain SaO<sub>2</sub>.

<sup>&</sup>lt;sup>†</sup>Deep sedation may be indistinguishable from general anesthesia and carries all the same risks.

**Figure 2-2** The Mallampati classification relates tongue size to pharyngeal size. It is based on the pharyngeal structures that are visible. Class 1: Visualization of the soft palate, fauces, uvula, anterior and posterior pillars. Class 2: Visualization of the soft palate, fauces, and uvula. Class 3: Visualization of the soft palate and the base of the uvula. Class 4: Soft palate not visible at all. (Modified from Mallampati SR, Gatt SP, Gugino LD, et al: A clinical sign to predict difficult tracheal intubation: A prospective study. Can J Anaesth 32:429–434, 1985.)

documentation are pertinent medical history, current medications, allergies (problems with sedative or analgesics), and review of systems (snoring or obstructive sleep apnea). The physical examination should focus on assessment of airway and cardiovascular system. Anatomic variants (macroglossia, micrognathia) and presence of a beard, dentures, or a short, arthritic neck should be noted. Direct evaluation of the patient's open mouth using the *Mallampati classification* measures how much the tongue obscures the uvula and soft palate (Fig. 2-2 and Table 2-3). Obtain and document an *informed consent* from the patient for both PSA and the procedure. Explain the sedation process, potential for failure, adverse effects, as well as alternatives to the procedure and the consequences of not providing sedation.

# PREPROCEDURE PATIENT PREPARATION

- Reconfirm the initial assessment and the patient's ASA classification.
- Document the fasting time.
- Check a pregnancy test on age-appropriate women.
- Make certain there is an adult to escort the patient home.
- Ask the patient to void, dress in a gown, and recline on the procedure bed.
- The IV line should be secured and functioning.
- Blood pressure cuff, cardiac monitor, and pulse oximeter should be applied and baseline vitals, including room air SaO<sub>2</sub>, documented.
- Emergency resuscitation equipment and medications should be functional and at the ready.
- A PSA monitoring flow sheet is used to record preprocedure, intraprocedure, and postprocedure data. Document start and completion times, medications and dosages administered, as well as the level of sedation achieved throughout the procedure (see flow sheets online at www.expertconsult.com).
- The practice of premedicating the patient with histamine type 2 blockers or proton pump inhibitors is no longer recommended because of the lack of evidence with regard to the efficacy of these

# Class I Class II Class III Class III Class III Class IV C

- drugs to diminish gastric acid secretion and subsequent risk of aspiration.
- Before sedating the patient, physician and assistant must take a
   "time out" to once again identify the patient, the intended procedure, and the site. Once the procedure has started, the patient should be encouraged to tell the operator about any unusual discomfort, shortness of breath, chest pressure, or itching.

# **TECHNIQUE**

- Position the patient as comfortably as possible for the procedure, using warm blankets and placing pillows under the head or knees.
- 2. Use the single dose of medication that will provide a maximum level of sedation required to perform the procedure. Multiple small doses create discomfort for the patient and may culminate in oversedation. For painful procedures, begin IV administrations with a short-acting narcotic. For painless but anxiety-producing procedures, there should be more emphasis on anxiolysis. Maintain verbal contact with the patient. Observe the patient for slurred speech, droopy eyelids, and calm affect. The patient should stir to verbal commands and be able to follow them. Remember that the effects should start within several minutes but may not peak for up to 7 minutes.
- 3. Begin the procedure once the patient has achieved the desired depth of sedation.
- 4. If the patient is not sedated adequately after a modest dose of narcotic, administer a small dose of a short-acting benzodiazepine and continue to observe for effects. Recall the synergistic efforts of these drugs.
- 5. Record vital signs every 5 minutes. The assistant should remain at the patient's bedside throughout the procedure to observe the response to sedation and to respond to any monitor alarms. The patient must be monitored continually for head position, level of consciousness, airway patency, and adequacy of respiration and oxygenation. Observation of ventilation is essential, especially when using supplemental oxygen, which will delay the detection of apnea by pulse oximetry.
- 6. Naloxone and flumazenil should be at the bedside in the event any reversal is required.
- 7. The depth of sedation should be assessed at frequent intervals during the procedure. If the sedation is too light the patient may express displeasure or experience discomfort, as well as develop tachycardia or hypertension. If sedation is too deep the patient may develop periods of apnea; the oxygen saturation (SaO<sub>2</sub>) will decrease and trigger the monitor alarm. Also, if side-stream endtidal CO<sub>2</sub> is used, the earliest sign of respiratory compromise would be a steady rise of the end-tidal CO<sub>2</sub> above 40 mm Hg. Finally, the patient's Aldrete score (see flow sheet online at www. expertconsult.com) will decrease if sedation is too deep. If at any time during the procedure there is a change in or deterioration of the patient's condition, either suspend or abort the procedure, assess the patient, and commence any resuscitation.

# **MEDICATIONS**

There are several medications in the armamentarium of PSA. The physician must understand the pharmacology of these drugs and the appropriate settings in which to use them.

A short-acting analgesic should be used at the onset. Fentanyl has a very good safety profile with a rapid onset and short duration of action. It does not cause the extent of cardiorespiratory depression that is typical of other opioids. However, its side effects are magnified with benzodiazepines (Table 2-4).

If anxiolysis is the goal of PSA, fentanyl combined with midazolam provides a minimal level of sedation that is ideal for such procedures as cardioversion, endoscopy, lumbar puncture, and certain wound repairs. When moderate sedation is desired for particularly painful procedures, fentanyl can be used with etomidate to create relaxation

<sup>\*</sup>See also Figure 2-2.

TABLE 2-4 Commonly	Used Medications	for Procedural Sedation and	Analgesia		
Medication	Class	Description	Initial IV Dose	Repeat Dose	Minimum Interval
Etomidate (Amidate)	Sedative-hypnotic	Rapid onset Short duration	0.1 mg/kg	0.1 mg/kg	5 min
Fentanyl (Sublimaze)	Opiate	Short acting	I μgm/kg, up to I00 μg	25–50 μg	5 min
Flumazenil (Romazicon)	lumazenil (Romazicon)  Benzodiazepine antagonist		0.2 mg	0.2 mg, up to 1 mg total	I min
Midazolam (Versed)	Benzodiazepine	Short acting Sedation/amnesia	I–2 mg	0.5–1 mg, up to 5 mg	5 min
Methohexital (Brevital)	Ultra-short-acting barbiturate	Nonanalgesic amnesia	0.75-1 mg/kg	0.5 mg/kg	2 min
Naloxone (Narcan) Propofol (Diprivan) Atropine	Opiate antagonist Sedative-hypnotic Anticholinergic Antiarrhythmic	Reversal agent for opiate Rapid onset Treatment of symptomatic bradycardia; decrease secretions	0.2–0.4 mg I mg/kg 0.4 mg	0.2 mg 0.5 mg/kg 0.4 mg, 3 mg max	2–3 min 3–5 min 3–5 min
Diphenhydramine (Benadryl)	Antihistamine Anticholinergic	Treats anaphylaxis; sedative; antiemetic	25 mg	25 mg	5-10 min
Metoclopramide (Reglan)	Central and peripheral dopamine antagonist	Antiemetric	10 mg	_	_
Ondansetron (Zofran)	Serotonin (5-HT <sub>3</sub> ) receptor antagonist	Antiemetic	4 mg	4 mg, 16 mg max	5–10 min

for closed reductions of joint dislocations or fractures. *Propofol* can be used for moderate or deep sedation. It has no analgesic properties and should be used with fentanyl. It is safest to deliver propofol as a continuous infusion that can be discontinued if any adverse reaction occurs. At low doses, *methohexital* produces a state of unconsciousness while preserving protective airway reflexes. It is purely an amnestic agent, and careful use with opioids is advised. Hypotension and histamine release are significant side effects.

Ketamine is a dissociative agent that has a long history of use for pediatric PSA. The data supporting the use of ketamine in adults are very few owing to the increased incidence of hallucinations during emergence from the drug.

## **COMPLICATIONS**

Several factors are associated with adverse outcomes during PSA. In addition to the known effects of the drugs themselves, there are patient factors, inadequate preprocedural evaluation, drug–drug interactions, drug dosing errors, and inconsistent monitoring and observation.

Respiratory depression is the most common and profound adverse effect. All of the drugs used inhibit respiratory drive to some degree. The synergistic effects that occur when the drugs are combined can magnify the inhibition of the respiratory system. Should the SaO<sub>2</sub> fall below 90%, the procedure should be suspended and the patient evaluated. In addition, chest wall and glottic rigidity are catastrophic side effects of fentanyl that can occur when a high dose of the drug is injected rapidly. Under these circumstances the patient may require paralysis and mechanical ventilation until the symptoms resolve.

Sympathetic output from the central nervous system is similarly suppressed by all of the PSA drugs and can result in *bradycardia* and *hypotension*. Furthermore, there is a preponderance of patients who take  $\beta$ -adrenergic blockers and calcium channel blockers, which increase the risk for *dysrhythmias* and cardiovascular collapse during PSA. *Atropine 0.4 mg* IV push is used to treat symptomatic bradycardia (i.e., bradycardia associated with hypotension or heart block).

Nausea and vomiting are usually due to opioids. Preventing unwanted gastrointestinal side effects is important when the patient's sensorium is depressed because emesis could lead to aspiration. Noxious gastrointestinal symptoms also make for an unpleasant experience for the patient. Zofran 4 to 8 mg IV is an excellent antiemetic.

Should the patient experience any *itching* or if *urticaria* becomes apparent (*allergic reactions*), *diphenhydramine 25 mg* IV should be administered. Auscultate the lungs for wheezing and check vital signs. Inhaled bronchodilators, IV corticosteroids, and subcutaneous epinephrine are appropriate for the management of allergic reactions and anaphylaxis.

In rare instances, *paradoxical reactions* to benzodiazepines can occur. Malignant hyperthermia must also be kept in mind as a potential complication.

# POSTPROCEDURE RECOVERY AND PATIENT EDUCATION

Recovery should occur in a place where there is adequate cardiopulmonary monitoring and trained personnel for direct observation because the patient continues to be at risk for development of drugrelated complications. If reversal agents are administered, continuous observation is required until sufficient time has elapsed for the last dose to wear off, thus avoiding resedation. The Aldrete score uses five criteria to determine a level at which it is safe to discharge the patient. The parameters include a measure of blood pressure and  $SaO_2$  and an evaluation of the patient's mental status, airway patency, and motor function. (See flow sheet online at www. expertconsult.com.)

The patient's escort should be given both verbal and written instructions that include postprocedure activities, diet, and medications. Give the patient the following advice:

- Do not drive a car or operate hazardous equipment until the next day.
- Do not make important decisions or sign legal documents for 24 hours.
- Do not take medications, unless your physician has prescribed them specifically, for the next 24 hours.
- Avoid alcohol, sedatives, and other depressant drugs for 24 hours.
- Notify your health care provider of pain, severe nausea, difficulty breathing, difficulty voiding, bleeding, or other new symptoms.

### **PATIENT EDUCATION GUIDES**

See patient education and consent forms and PSA monitoring flow sheets online at www.expertconsult.com.

#### **CPT/BILLING CODES**

See the CPT definition for moderate sedation discussed earlier.

36000 Introduction of needle or intracatheter, vein

90760 IV therapy 1 hour

99144

90774 IV injection (use in conjunction with J codes for drugs)

94760 Noninvasive ear or pulse oximetry for oxygen saturation

94761 Noninvasive single interpretation

97761 Noninvasive, multiple interpretations

Sedation services provided by the same physician performing the diagnostic or therapeutic service that the sedation supports requiring the presence of an independent observer including monitoring of cardiorespiratory function (pulse oximetry, ECG, and blood pressure), age 5 years or older, first 30 minutes. When providing moderate sedation, the following services are included and *not* reported separately:

- Assessment of the patient (not included in intraservice time)
- Establishment of IV access and fluids to maintain patency, when performed
- Administration of agent(s)
- Maintenance of sedation
- Monitoring of SaO<sub>2</sub>, heart rate, and blood pressure
- Recovery (not included in intraservice time)

Intraservice time starts with the administration of the sedation agent(s), requires continuous face-to-face attendance, and ends at the conclusion of personal contact by the physician providing the sedation.

99145 Each additional 15 minutes of intraservice time

99147 Moderate sedation services provided by a physician other than professional performing the procedure, first 30 minutes, age 5 years or older

99150 Each additional 15 minutes

# EPIDURAL ANESTHESIA AND ANALGESIA

Peter W. Grigg

Epidural anesthesia (i.e., complete relief of pain and significant motor block) and analgesia (i.e., the relief of pain only, with as little motor block as possible) can be accomplished by injecting opiates, local anesthetics, or a combination of these medications into the epidural space. An epidural is an extremely versatile procedure; it may be used to enhance the birthing experience or to provide anesthesia or analgesia during or after surgical procedures. For prolonged analgesia, a catheter may be left in the epidural space for several days to allow additional medication to be injected by repeated bolus, patient-controlled epidural anesthesia (PCEA) pump, or controlled continuous infusion.

From an anesthetic perspective, the *level* of anesthesia refers to an anatomic level or segment of effect (e.g., up to the level of the umbilicus [T10] or the level of the xiphoid [T8]), whereas *depth* refers to the amount of sensation or motor activity remaining. Depth of blockade is determined by choice of drugs and concentrations. Segmental level of anesthesia or analgesia can be controlled by the level of the injection, the volume of solution injected, as well as other factors (see the note after the Technique section), and the depth can be increased or decreased as the clinical situation dictates. Such control is one of the advantages of epidural anesthesia over other forms of regional anesthesia.

Clinicians administering epidural anesthesia must have a good understanding of not only the relevant anatomy and needle placement techniques, but the pharmacology and physiology involved. The clinician must be familiar and experienced with the diagnosis and management of possible complications. A review of and familiarity with the updated American Society of Anesthesiologists (ASA) Practice Guidelines for Obstetric Anesthesia (2007) and the ASA Difficult Airway Algorithm are highly recommended for medical professionals providing epidural services to obstetric patients. Epidural anesthesia or analgesia should be performed only in a hospital, surgery center, or facility where equipment and adequately trained personnel are available to manage any and all possible complications. The equipment available should be comparable with that of a hospital operating room.

EDITOR'S NOTE: Although there is general agreement that epidural anesthesia is safe and is the most effective method of pain relief in labor, there has been some controversy regarding possible side effects. Meta-analyses attempting to determine whether epidurals increase the risk for cesarean section are conflicting, but the majority of current evidence suggests they do not. However, there is consensus among studies that epidurals prolong labor—the first stage of labor by 12 minutes and the second stage of labor by 42 minutes. There is also consensus that epidurals increase the need for assisted delivery and the likelihood of maternal fever. (The cause of epidural-associated maternal fever is unknown.) Fetal heart rate changes are also common with epidurals during labor. Although the cause of heart rate changes is not known, one theory suggests reduced

uterine blood flow from maternal hypotension as the mechanism. Intravenous (IV) fluid preloading (volume expansion) may help reduce the risk of maternal hypotension. However, IV fluid preloading must be performed cautiously or slowly in patients with pregnancy-induced hypertension.

#### **ANATOMIC CONSIDERATIONS**

The spinal canal contains the spinal cord, its coverings (i.e., pia mater, arachnoid mater, dura mater), and cerebrospinal fluid. The pia mater is closely attached or adherent to the spinal cord. The dura mater is the separate, toughest, and outermost covering of the spinal cord. The arachnoid membrane is a delicate membrane interposed between the dura mater and the pia mater. It is separated from the pia mater by the subarachnoid space, which contains the cerebrospinal fluid.

The epidural space is a potential space, external to the dura mater and located between the dura mater and the ligamentum flavum (connective tissue covering the vertebrae; Fig. 3-1). Although the epidural space is a potential space, it is filled with spongy connective tissue, fat, and blood vessels. This allows for solutions injected into the space to flow freely in all directions and to bathe the nerve roots as they exit the spinal canal.

#### **PHYSIOLOGIC CONSIDERATIONS**

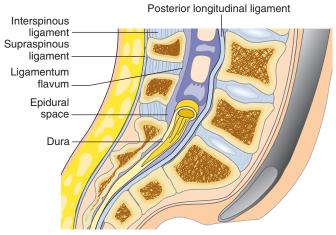

When an epidural is used in labor and delivery, it is important to remember that visceral pain from uterine contractions is partly conducted through the sympathetic nervous system. Impulses travel through the inferior, middle, and superior hypogastric plexuses to the sympathetic chain. This chain then connects to the spinal cord through the 10th, 11th, and 12th thoracic nerves. Any effective analgesic solution must spread cephalad enough to affect these levels.

# **INDICATIONS**

- As an alternative to general or spinal anesthesia for selected surgical procedures
- Requested by patient or suggested by clinician (e.g., to avoid maternal fatigue) for labor and delivery
- Postoperative analgesia

**NOTE:** Epidural analgesia should not be withheld on the basis of achieving an arbitrary cervical dilation.

**NOTE:** Continuous epidural analgesia is being used more and more for obstetrics and postoperative analgesia; however, spinal anesthesia is still the most commonly used regional technique for surgical procedures.

**Figure 3-1** Anatomy of the vertebral column and its contents in the lower lumbar and upper sacral regions. (Redrawn from Moore DC: Regional Block, 4th ed. Springfield, III, Charles C Thomas, 1979.)

# **CONTRAINDICATIONS**

- Patient declines
- Localized infection at the puncture site
- Severe, uncorrected hypovolemia
- Blood dyscrasias; coagulopathy; prolonged international normalized ratio (INR), prothrombin time (PT), or activated partial thromboplastin time (APTT); thrombocytopenia
- Anticoagulant therapy (e.g., heparin, warfarin, enoxaparin [Lovenox], fondaparinux [Arixtra], clopidogrel [Plavix])
- Allergy to specific epidural agents
- Spinal abnormalities, including scoliosis and other structural abnormalities
- Active systemic infection
- Lack of proper resuscitative equipment, skills, or trained staff
- Preexisting neurologic diseases (amyotrophic lateral sclerosis [ALS], other degenerative nerve diseases, polio)
- Preoperative headache (relative)
- Aortic stenosis
- Anemia

### **EQUIPMENT**

- Disposable sterile gloves
- Equipment for the clinician to observe universal blood and body fluid precautions
- Disposable epidural tray containing the following:
  - 1. Appropriate prep solutions, swabs, and sterile 4 × 4 gauze pads
  - 2. Disposable drapes
  - Epidural catheter, threading assist guide, and syringe adapter attachment
  - 4. Syringes
    - a. Plastic Luer-Lok (3 mL) for local infiltration of lidocaine 1%
    - b. Plastic syringe (20 mL) for administration of epidural agent
    - c. Glass Luer-Lok procedural syringe (5 mL) filled with saline for loss-of-resistance technique (Fig. 3-2)
  - 5. Needles
    - a. Skin puncture needle (18 gauge)
    - b. Tuohy epidural needle (18 gauge) or other epidural needle
    - Filter needle (19 gauge) for drawing solutions into the syringes
    - d. Skin wheal needle (25 or 27 gauge)
  - 6. Filter (0.2  $\mu$ m) and filter straw (4 inch)
  - 7. Medications
    - a. Lidocaine 1% (5-mL vial) for local infiltration

- b. Sodium chloride 0.9% injectable (10-mL ampule)
- c. Test dose lidocaine 1.5% injectable, with epinephrine 1:200,000 (5-mL vial)
- d. Epinephrine injectable 1:1000 (1-mL vial)
- Epidural medications (Table 3-1)
- Patient-monitoring equipment (e.g., automated blood pressure [BP] device, continuous electrocardiogram [ECG] monitor, pulse oximeter, fetal monitor [if used for obstetrics])
- Emergency and resuscitative equipment (e.g., suction, Ambu-bag, oxygen, defibrillator) as well as an anesthesia machine
- Emergency and other drugs not included in the epidural kit:
  - 1. Ephedrine 5% (1 mL) for use if hypotension develops (usual dose to treat hypotension is 10 mg [0.2 mL] IV)
  - 2. Phenylephrine (Neo-Synephrine)
  - 3. Atropine
  - 4. Diphenhydramine (Benadryl)
  - 5. Metoclopramide (Reglan), ranitidine (Zantac), and Bicitra (a nonparticulate antacid; the generic is sodium citrate and citric acid solution 3 g/2 g per 30 mL)
  - 6. Diazepam or midazolam

NOTE: A 1% solution equals 10 mg/mL.

# **Epidural Agents: Local Anesthetics**

The two most commonly used local anesthetics for epidural anesthesia are lidocaine and bupivacaine (see Table 3-1). Lidocaine has a rapid onset (5–15 minutes) and lasts 1 to 2 hours, whereas bupivacaine has a slower onset of action (10–20 minutes) and a longer duration of action, lasting 2 to 4 hours. In general, increasing the concentration of the drug while maintaining the same volume decreases the latency (time to onset of anesthesia). The addition of epinephrine to lidocaine (available premixed 1:200,000 with lidocaine) or to 0.25% (or less) bupivacaine appears to increase the duration of action.

Bupivacaine is widely used for both obstetric and surgical epidural anesthesia and analgesia. Bupivacaine 0.25% provides adequate sensory analgesia with minimal motor blockade for 1 to 3 hours, and it is well suited for both obstetric and postoperative analgesia (Table 3-2). When used at 0.5% concentration, bupivacaine produces significant motor blockade. Because of toxicity at higher levels, bupivacaine 0.75% is not recommended for use in obstetrics.

Levobupivacaine (Chirocaine) is a newer agent that is similar to bupivacaine in duration and action but with less central nervous system (CNS) and cardiac toxicity. Another agent, ropivacaine (Naropin), has less cardiotoxicity than bupivacaine but more than lidocaine. In addition, ropivacaine has a significantly higher threshold for CNS toxicity than bupivacaine. In studies, 15 to 30 mL ropivacaine 0.5% provided epidural anesthesia comparable to bupivacaine 0.5% for cesarean section; however, the duration of motor blockade was shorter with ropivacaine.

When lumbar epidural anesthesia is used for surgical procedures, initial volumes of 10 to 20 mL are recommended in adult patients, depending on the concentration of anesthetic and the desired level of anesthesia. Sensory levels are then checked and the dose adjusted accordingly. Additional incremental doses are administered through the epidural catheter as needed. Lower initial volumes (6 to 10 mL) are usually adequate for analgesia in the obstetric patient.

**NOTE:** The clinician should always use preservative-free local anesthetics and narcotic agents specifically formulated for spinal or epidural anesthesia.

#### **Epidural Agents: Opiates**

Anesthetic agents tend to cause motor blockade. Although they do not cause motor blockade, epidural opioids alone are not as effective as dilute concentrations of local anesthetics for anesthesia or analgesia. However, when opiates are used in combination with local

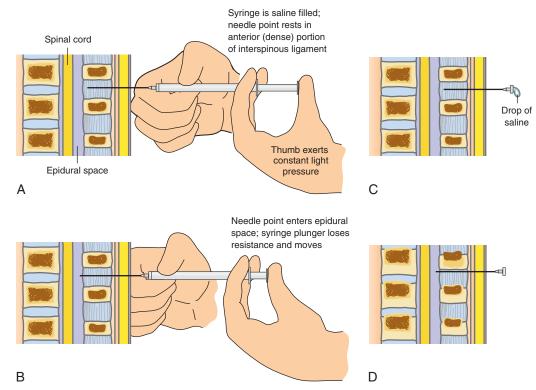

Figure 3-2 Loss-of-resistance and hanging-drop methods of ascertaining when the point of the needle rests in the epidural space. **A,** Needle rests in interspinous ligament. **B,** Syringe plunger loses resistance when needle enters epidural space. **C,** Saline-filled syringe has been removed, leaving a hanging drop. **D,** Hanging drop disappears when needle enters epidural space. (Redrawn from Moore DC: Regional Block, 4th ed. Springfield, III, Charles C Thomas, 1979.)

TABLE 3-1 Lo	ABLE 3-1 Local Anesthetics Commonly Used for Epidural Anesthesia												
Agent	Concentration (%)	Dose (mL)	Dose (mg)	Onset (min)	Duration (hr)	Sensory Block	Motor Block

**TABLE 3-3** Concentrations of Bupivacaine with or without Opioids for Labor Analgesia (Bolus Injection)

Bupivacaine Concentration (%)*	Dose (mL)	Opioid	Result
0.5	5–10	None	Both sensory and motor blockade
0.25	10–15	None	Sensory and partial motor blockade
0.125	10–15	Fentanyl I–3 μg/mL	Sensory and minimal motor blockade
0.06	10–15	Sufentanil 0.5 μg/mL	Analgesia and no motor blockade

<sup>\*</sup>The higher concentrations are being used less frequently for labor analgesia. The trend is for use of higher-volume lower local concentrations.

anesthetic agents, they allow for a reduction in the necessary concentration of the anesthetic agents, thereby minimizing motor blockade. This makes epidural opioids particularly useful in situations where motor blockade is undesirable (e.g., labor, control of postoperative pain). Table 3-3 shows doses and effects of combining bupivacaine and opioids for control of labor pain.

#### PREPROCEDURE PATIENT PREPARATION

A focused history (general maternal health, anesthesia problems, drug allergy, relevant obstetric issues, current medications, and NPO status) and physical examination should be performed with special attention to the airway, blood pressure, heart, lungs, and back for anatomic deformities or skin infection. Expert witnesses in medical liability cases often note a lack of preblock examination by the anesthesiologist. Laboratory studies are obtained on an individualized basis and should include a coagulation profile if indicated.

The patient should be informed of the available anesthesia and analgesia options. A fact sheet can be given to the patient to read before surgery or before the procedure is performed (see the sample patient education form available at www.expertconsult.com) or, for obstetric patients, before the onset of labor. For obstetric care, patients should be informed that any anesthetic procedure is optional and that there are associated risks. Preferably, the fact sheet is given to the patient as a part of the prenatal care. Desired anesthesia or analgesia should be included in the patient's birth plan.

Shortly before performing an epidural, the clinician should answer any questions, review the options again with the patient, including the benefits and specific risks, and obtain signed informed consent. Follow local NPO guidelines (usually nothing to eat or drink 8 hours before the scheduled procedure). Early and ongoing communication between the obstetrician or surgeon and the anesthesiologist is vital, particularly when significant anesthetic, obstetric, or surgical risk factors have been identified.

## **TECHNIQUE**

- Consider giving nonparticulate antacids, H<sub>2</sub> blocker, and metoclopramide 30 minutes before an epidural if a cesarean delivery or postpartum tubal ligation is being performed.
- Informed consent and permission forms should be signed and in order.
- Establish IV access with a 20-gauge or larger catheter and give a bolus of 500 to 1000 mL of IV fluids. The patient should be well hydrated before the procedure to minimize the risk of hypotension.

NOTE: Administer the IV fluids slowly in patients with pregnancy-induced hypertension.

- 4. Secure the continuous BP, ECG, and pulse oximetry monitors on the patient and record the initial values. Cycle the BP monitor to observe carefully for hypotension by measuring the BP every 2.5 minutes. Vital signs should be recorded on the anesthesia chart at least every 5 minutes. All medications, doses, routes, and times administered must be noted on the record. For obstetric patients, fetal monitoring should be used.
- Open the disposable epidural kit and mix the appropriate solutions. Use the filtered needle to draw the solutions that will be administered epidurally. All epidural medications must be preservative free.
- 6. Place the patient in either the sitting or the lateral position, with the back and neck flexed and the spine straight and not rotated. An assistant should stand in front of the patient during the procedure, helping the patient to remain in that position.
- 7. Locate the appropriate interspace. Perform the sterile prep and drape the area.
- 8. A midline approach through the L2 to L3, L3 to L4, or L4 to L5 interspace is most commonly used for epidural anesthesia. Administer local anesthesia (lidocaine 1%) to the interspace area by first making a skin wheal, then injecting into the deeper tissues at the angle the epidural needle will follow.
- 9. Preliminarily puncture just the skin with an 18-gauge needle to allow for later easy passage of the epidural needle.
- 10. Pass the Tuohy epidural needle through the skin, angling it appropriately to pass directly toward the spinal canal, until it has firmly passed into the interspinous ligament. Using either the loss-of-resistance technique (with air or saline) or the hanging-drop method (see Fig. 3-2), the needle is now advanced into the epidural space.

**NOTE:** The proper angle to direct the tip depends on which interspace is used. The proper angle is almost perpendicular at the L4 to L5 interspace (90 degrees), although it decreases to about 70 degrees at the L2 to L3 interspace. The proper location is usually just below the inferior border of the spinous processes. For epidural anesthesia, insertion angle and location are identical to those used for saddle block anesthesia; however, the depth of insertion is unique to each procedure.

- 11. Single-shot epidural injections may be used for surgical procedures of short duration. If a longer-duration procedure is anticipated or if postoperative pain relief is desired, place an epidural catheter. Catheter placement must be performed very carefully because improper placement can cause life-threatening complications (e.g., intravascular injection, or total spinal anesthesia if in the subarachnoid space). Rotate the needle so that the catheter will pass either cephalad or caudad as it exits the needle. Note the markings toward the hub of the epidural catheter that are usually 1 cm apart after the first mark. In most cases, the first mark is the same distance from the tip of the catheter as the needle is long. In other words, when inserting the catheter, after the first mark has passed into the needle hub, for every centimeter mark further that the catheter is advanced, the tip advances a centimeter into the spinal canal.
- 12. Place the tip of the catheter through the hub of the Tuohy epidural needle and advance it slowly through the needle and into the epidural space. A slight resistance is usually encountered as the catheter tip passes through the needle into the epidural space. Advance the catheter 5 cm into the epidural space. The needle is then slowly withdrawn over the catheter, and the catheter secured at the puncture site and along the back with tape. Tape the catheter in place after the patent sits up because the epidural catheter moves when changing from the flexed to straight up position, and may otherwise come out of the epidural space.

**NOTE:** The clinician should *never* attempt to withdraw the catheter while the needle is in place. The catheter may shear off,

leaving the distal segment in the epidural space. Never readvance the needle after the catheter is in place, for the same reason.

- 13. Secure the catheter hub so that it is easily accessible for injections from the head of the operating table. Fasten the syringe adapter filter to the proximal end of the catheter. Tape the hub to the epidural tubing and to the patient's gown to prevent dislodging with movement.
- 14. Administer the test dose through the catheter or through the needle hub if not using a catheter. The test dose is performed to detect either intravascular or subdural placement of the catheter or needle. Begin by aspirating to check for the presence of blood or cerebrospinal fluid. If either is present, the needle has been inserted improperly and must be corrected. Next, administer 2 to 4 mL of 1.5% lidocaine with 1:200,000 epinephrine. If the needle is intravascular, a noticeable increase in heart rate, BP, or both will usually be detected within 3 minutes after the injection. The patient may note tinnitus. Sensory and motor function of the lower extremities will be affected after 5 minutes if the catheter or needle is in the subdural space. If intravascular placement is detected, remove the catheter and repeat the procedure at a different interspace. If the catheter is intrathecal, then options exist: (1) remove and replace the catheter at a different interspace or (2) use as a continuous spinal catheter.
- 15. After the test dose has confirmed proper placement, the patient is ready for the epidural injection. Aspirate to check for the presence of blood or cerebrospinal fluid before each injection or before placing the patient on an infusion pump or PCEA pump. (Use of infusion pumps or PCEA pumps is beyond the scope of this chapter. Please refer to standard anesthesia textbooks for this information.) Check and record the level of analgesia after the injection. A relatively sharp object (e.g., a toothpick) can be used to do this. Do not use a needle.
- 16. Some anesthesiologists do a combined spinal/epidural technique, but this is not described here.

**NOTE:** The factors affecting the level of epidural analgesia include the level of the epidural injection; the volume and concentration of anesthetic solution used; the rate of injection; the addition of a vasoconstrictor; patient age, height, and physical condition; and the position of the patient.

#### **COMPLICATIONS**

- Hypotension
  - Ît is the most common cardiovascular complication of epidural anesthesia.
  - It is caused by widespread sympathetic block.
  - Hypovolemic patients are more susceptible to hypotension.
  - The clinician should treat significant hypotension with positioning, IV fluids, and an IV vasopressor if needed.

**NOTE:** Significant bradycardia may be treated with atropine.

- Subarachnoid injection: Injection of large volumes of anesthetic solution into the subdural or subarachnoid space may result in a high or total spinal block, with respiratory arrest, severe hypotension, and possibly cardiac arrest. These conditions must be recognized and treated immediately.
- Postspinal headache: Subdural puncture, always a risk when performing epidural anesthesia, carries a high risk for spinal headache, particularly in younger and pregnant patients. For severe or persistent headache, a blood patch may be necessary.
- Toxicity from anesthetic agents
  - See Chapter 5, Local and Topical Anesthetic Complications.
  - Accidental injection of local anesthetic into the bloodstream or anesthetic overdose may lead to systemic toxic reactions, including (1) CNS toxicity (which begins with numbness of tongue, lightheadedness, dizziness, tinnitus, blurred vision, disorientation, drowsiness, muscle twitching, and tremors, pos-

sibly progressing to convulsions); and (2) cardiovascular toxicity (initially a mild increase in BP and heart rate is observed, followed by hypotension). The clinician should treat initial hypotension with ephedrine. In severe cases the patient may experience an irreversible state of cardiovascular depression.

**NOTE:** For CNS toxicity, treat convulsions by (1) maintaining a patent airway and assisted or controlled ventilation; and (2) administering IV thiopental (Sodium Pentothal), midazolam, or diazepam. Intubation may be required.

- Local tissue toxicity is also possible (but it is rare when preservative-free anesthetic solutions are used).
- Respiratory complications, which can be caused by paralysis of intercostal muscles, and hypoxia or hypercarbia can occur, especially in patients with underlying respiratory disease (e.g., chronic obstructive pulmonary disease).
- Neurologic damage: Postepidural neurologic sequelae are due to (1) trauma; (2) anterior spinal artery syndrome (i.e., a syndrome resulting from damage or thrombosis of the anterior spinal artery caused by trauma from the epidural needle), which is almost always avoided by using a midline approach when inserting the needle; and (3) epidural hematoma.

NOTE: Because of decreased peripheral sensation, the patient is at increased risk of lower extremity injury as long as the epidural is in place. Risk of neural injury in the operating room can be kept to a minimum through careful patient positioning. After surgery, patients must be followed closely to detect potentially treatable sources of neurologic injury, including expanding spinal hematoma or epidural abscess, constrictive dressings, improperly applied casts, and increased pressure on neurologically vulnerable sites. A neurologist or a neurosurgeon should evaluate new neurologic deficits promptly to formally document the patient's evolving neurologic status, arrange further testing or intervention, and provide long-term follow-up.

- Catheter complications
  - Epidural catheters may be inadvertently inserted into a blood vessel or into the subarachnoid space. The test dose is used to avoid this possibility and to prevent placing a large dose of anesthetic into either the circulation or the subarachnoid space. Epidural catheters can also migrate into blood vessels and the subarachnoid space, so watch for complications that may occur shortly after insertion.
  - The distal portion of the catheter may break off in the epidural space. This may occur if an attempt is made to withdraw the catheter through the epidural needle. It may also occur if the needle is readvanced after the catheter is deployed. If the catheter will not advance through the needle, remove the needle and catheter together and repeat the procedure at another interspace.

## **CPT/BILLING CODES**

- 62273 Injection, lumbar epidural, of blood or patch
- 62278 Injection of diagnostic or therapeutic anesthetic or antispasmodic substance (including narcotics); epidural, lumbar or caudal, single
- 62279 Injection of diagnostic or therapeutic anesthetic or antispasmodic substance (including narcotics); epidural, lumbar or caudal, continuous
- 62311 Epidural, lumbar, single
- 62319 Epidural, lumbar, continuous

### **ICD-9-CM DIAGNOSTIC CODES**

For ICD-9-CM codes for other surgical procedures, see the appropriate chapter.

V22.2 Pregnant state, NOS

650 Spontaneous vaginal deliveries

A fifth digit (represented by the \* symbol in the following codes) is used to denote the current episode of care for codes 640 to 648 and 651 to 669. Following are the digits used and the episodes of care they represent:

0 = Unspecified

1 = Delivered with or without mention of antepartum condition

2 = Delivered with mention of postpartum complication

3 = Antepartum condition or complication 4 = Postpartum condition or complication

644.2\* Premature labor with delivery (less than 37 weeks)

652.2\* Breech presentation

653.5\* Unusually large fetus causing disproportion

660.4\* Shoulder dystocia

The following are codes related to deliveries with forceps or vacuum:

659.7\* Abnormality in fetal heart rate or fetal distress

662.2\* Prolonged second stage of labor

The following are codes related to episiotomy, episiotomy repair, and repair of low vaginal lacerations:

664.0\* First-degree perineal laceration

664.1\* Second-degree perineal laceration

664.2\* Third-degree perineal laceration

664.3\* Fourth-degree perineal laceration

664.4\* Unspecified perineal laceration

The following are codes that relate to pain:

719.4 Joint pain

724.5 Back pain

729.5 Limb or leg pain

**NOTE:** More specific locations will usually be reimbursed at higher levels.

307.80 Psychogenic pain, site unspecified

307.89 Psychogenic pain, other (This code can be used to indicate pain in most areas.)

# LOCAL ANESTHESIA

Gerald A. Amundsen

The administration of local anesthesia is an extremely important practice in most clinical settings. Most wounds, traumatic and surgical, require some form of anesthesia before repair in order to maintain patient comfort and satisfaction. Over 100 million wounds are repaired in the United States each year, so it is imperative that most clinicians be well accustomed to the medications and techniques used to administer the medications.

The underlying action of local anesthetics is to prevent the generation and conduction of nerve impulses at the molecular level. The overall effect of an anesthetic is to reduce pain associated with trauma or procedures, and this effect is significantly affected by factors such as blood supply, the size of the area to be anesthetized, and the location of the wound in terms of nerve ending size and density. The fingers, toes, genitals, perianal area, and nose are especially sensitive. Patient factors such as infection, anxiety, and chronic disease (e.g., diabetes, peripheral vascular disease, obesity) also affect the success of the anesthetic. To achieve successful anesthesia, the clinician must be able to make decisions and react based on all of these factors. (Also see Chapter 10, Topical Anesthesia.)

#### **INDICATIONS**

- To relieve pain from a procedure (incision) or trauma (laceration/ fracture)
- Diagnostic nerve blocks to isolate pathology

See Tables 4-1 and 4-2 for a selection of local anesthetics and their characteristics, and Box 4-1 for selection criteria for local anesthetics.

# **RELATIVE CONTRAINDICATIONS**

- "Known" sensitivity to amide anesthetic medications (lidocaine, mepivacaine, bupivacaine) has never been reported and so is a relative contraindication. The older ester anesthetics (procaine, tetracaine) are more likely to cause true allergic reactions. Fortunately, there is no cross-reactivity between the classes, so the individual with known sensitivity to the ester anesthetics is not likely to experience a similar reaction with the amide group. The parabens preservatives used to prolong shelf life in multidose vials of amide anesthetics may induce sensitivity reactions similar to those of the ester group. Parabens are most likely the cause of the "allergy" ascribed to the amides. However, the incidence of parabens allergy is also quite low. If there is a concern about an allergy, use single-dose vials of the amide anesthetics that lack preservative and are inexpensive.
- History of central nervous system (CNS) symptoms (e.g., seizure, tremor, tinnitus) associated with anesthetic toxicity.
- History of cardiovascular reactions (e.g., hypotension, bradyarrhythmia) associated with previous anesthetic use.
- Epinephrine, frequently used in local anesthetics to prolong the action as well as to decrease the blood flow, may cause a variety

of reactions either directly, in association with other medications the patient uses, or as a result of other existing comorbidities.

- Epinephrine generally should also be avoided, because of vasoconstrictive properties, in the distal extremities (i.e., fingers, toes, penis, nose, earlobes), in contaminated wounds, or when the viability of a skin flap is in question.
- Patients with known peripheral vascular disease may have an exaggerated vasoconstrictor response to epinephrine. Extreme care should be taken if local anesthetics with vasoconstrictors are used in patients with diabetes, hypertension, arteriosclerosis, thyrotoxicosis, heart block, or cerebral vascular disease.
- If a skin flap has marginal viability or if blood flow to a flap is compromised, epinephrine should not be used.
- If a wound is contaminated, epinephrine may increase the likelihood of infection because of the diminished blood flow.
- Do not use epinephrine in patient taking monoamine oxidase inhibitors.

# **EQUIPMENT**

Supplies necessary for the local administration of anesthetic are typically inexpensive and readily accessible.

- Anesthetic agents of choice (see Table 4-1 and Box 4-1)
- 18-gauge needle to draw up solution
- 25- to 30-gauge needles of various lengths
- Syringes (1–10 mL)
- Antiseptic (alcohol, povidone-iodine, chlorhexidine) to clean the vial top and the clinical area
- Sodium bicarbonate 7.5% (Neutra-Caine) or sodium bicarbonate 7% to 10% for buffering the anesthetic if desired to reduce the pain of injection (see later discussion)

EDITORS' NOTES: (1) In equipping the office, it is unnecessary to store every type of anesthetic at every concentration, and it is also unnecessary to stock the office with every size and length of needle. It is more practical and economical for the physician to be familiar with the equipment of choice and to stock the office according to preference. Typically, a long- and short-acting anesthetic with and without epinephrine and a few sizes of needle should suffice for most offices. (2) Melman and Siegel (1999) have shown that it is perfectly acceptable to draw up buffered anesthetic solutions in syringes up to 14 days before use. When stored at room temperature, there is no increased bacterial contamination or growth, and the anesthetic still functions. We used to pull up our syringes at the beginning of the day and then discard them at the end of the day, but there is no need to do this. We now fill numerous 1-mL syringes, date them, and continue to use them throughout the week. It is much more efficient for the nurse to pull up multiple syringes than to do just one at a time. It is not efficient for the physician to spend time pulling up anesthetic into the syringe! (3) Advanced Meditech International (AMI) has designed a small anesthetic bottle holder that mounts on the wall (VE-11 Handzfree Anesthetic Bottle

TABLE 4-1 Lo	cal Anesthetic Agents				
Туре	Name	Concentration (%)	Onset	Duration*	Maximum Adult Dose

# Box 4-1. Selection of Local Anesthetics and Effects

# Lidocaine (Xylocaine) without Epinephrine (1% to 2%)

Can cause vasodilation

Can last 30 to 60 minutes depending on site or vascularity Use in contaminated wounds

Use in fingers, nose, penis, toes, earlobes

Use if vascular disease is present or if patient is

immunocompromised

Use if there are cerebrovascular or cardiovascular risks Use for nerve block

#### Lidocaine (Xylocaine) with Epinephrine (1% to 2%)

Causes vasoconstriction

Has longer duration

Use in highly vascular areas to improve visualization of field Use in clean wounds

In general, do not use on fingers, nose, penis, toes, and earlobes

#### Bupivacaine (Marcaine)

For longer duration

For nerve blocks

Holder; Fig. 4-1). The cost is around \$40, but in our office it is indispensable. It holds the anesthetic where it is readily available and makes filling syringes an easy task. It also allows the entire staff to see how much anesthetic is left in the bottle. There is nothing more frustrating than pulling out the drawer with the anesthetic solution and finding that the bottle is empty!

# **OPTIONS FOR ALLERGIC PATIENTS**

- Use a cooling agent (e.g., ice cube, ethyl chloride).
- For small lesions, use no anesthetic.
- Use single-dose vials instead of multidose vials to avoid the parabens preservatives.
- Use bacteriostatic saline alone.
- Substitute an amide for an ester (if offending agent can be identified)
- Use diphenhydramine (Benadryl). Inject 10 to 50 mg in the usual fashion (50 mg/mL diphenhydramine mixed with 4 mL of normal saline).

## PREPROCEDURE PATIENT PREPARATION

Patients should be made aware of the anesthesia plan (local, digital block, nerve block, topical) and the potential discomfort they may briefly experience. A standard consent form is used for whatever procedure is to be performed. The risks include allergic reaction to the anesthetic, infection, bleeding, damage to the area resulting in ischemia (if epinephrine or other vasoconstrictors are used), and systematic absorption of the local anesthetic.

**Figure 4-I** Anesthetic bottle holder. (Courtesy of Advanced Meditech International, Inc.; VE-11 Handzfree Anesthetic Bottle Holder.)

<sup>\*</sup>Duration of action for adults and older children; prolonged duration of action in neonates and young children possible.

<sup>&</sup>lt;sup>†</sup>No known allergic reaction to the amides. If allergic reaction apparent with use, consider parabens preservatives as the cause. Use single-dose vials of anesthetics to avoid parabens.

# **GENERAL TECHNIQUES**

- The top of the vial is wiped with alcohol, and the desired volume of anesthetic is withdrawn using an 18-gauge needle. Typically, 5 to 10 mL should suffice for most procedures, although less than 1 mL is usually enough for simple shave or punch biopsy procedures.
- 2. Discard the 18-gauge needle and replace it with an appropriately sized needle for the location and type of procedure. For most office procedures, a 27- or 30-gauge needle with a length of 1 or 1.5 inches is appropriate.
- 3. The local injection may be intradermal (creating a wheal) or subcutaneous (deep to the skin), depending on the intended procedure. Advance the needle to the desired location and draw back on the plunger before injecting to avoid systemic effects associated with injecting directly into a vessel. If there is blood return on aspiration, reposition the needle, aspirate again, and inject if there was no blood return during aspiration.
- 4. Before any digital or other block, a review of the related anatomy is recommended. In the case of digital blocks, it is important to remember the location and number of nerves supplying each digit (Fig. 4-2). (See Chapter 8, Peripheral Nerve Blocks and Field Blocks.)

# **COMMON ERRORS**

- Injection while advancing the needle can result in systemic complications from introduction of the anesthetic directly into the vascular system. Inject only while withdrawing the needle.
- Inadequate anesthesia may be the result of failure to wait for the agent to work effectively. Allow time for the drug to diffuse and achieve the desired effect (4–5 minutes). If the injection is intradermal (causing a wheal), it will have a more rapid onset. If deeper (subcutaneous), it will take longer to achieve its effect.
- Injection directly into an area of infection will not achieve good anesthesia and may contribute to spread of the infection. Do not inject into an area of infection. Rather, inject around the area in a field block pattern (Fig. 4-3), and do not use epinephrine in areas near infection.
- Although there is no proof that injection directly into a suspected cancer will spread the cancer along the needle track, injection into or through a suspected cancer should be avoided if possible.
- Injection of too much anesthetic may distort a lesion in a way that inhibits the accuracy and completeness of the excision or destruction. It may also mask a lesion and make it difficult to palpate and find if it is below the skin. Use a field block (see Fig. 4-3) to avoid the lesion while achieving anesthesia.

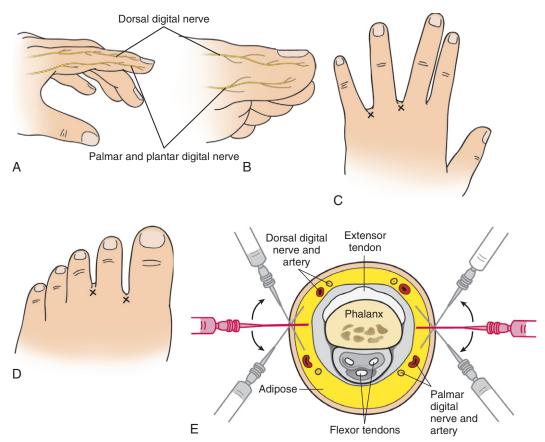

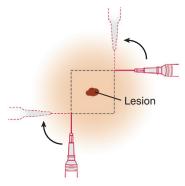

Figure 4-2 The anatomy of a digital block. In the finger (A) and toe (B), there are four nerves to block in order to obtain a successful digital block. A dorsal and palmar branch on each side of the digit needs to be blocked. If the proper sites of infiltration are chosen (C, finger, or D, toe), the four nerves should be well anesthetized. First, the web space on both sides of each digit is injected. Insert the needle parallel to the digits, directed toward the hand or foot. Insert I to 2 cm and inject I to 2 mL of anesthetic. Repeat on the other side. After the web space is infiltrated, insert the needle perpendicular to the base of the digit on each side of the digit. Insert until the needle touches bone. Withdraw a few millimeters and inject I mL of anesthetic (red needle and syringe). It is also helpful to then perform a "ring block" (E). Inject from the midline on top to the midline on the bottom from both sides to complete a "ring" around the entire digit (gray needle and syringe). A digital block may take several minutes to take effect because there is so much accessory innervation. In the case of a severely inflamed paronychia, or an ingrown toenail in which the nail must be partially or entirely removed, additional local anesthetic may still be necessary just proximal to the site of inflammation to eliminate pain and to allow the removal. It is best to avoid vasoconstrictor agents in local anesthetics for digital blocks. In addition, care should be taken to avoid systemic injection. See Figure 8-2 for more anatomic details.

**Figure 4-3** Field block. Inject at 90-degree angles on both sides of the skin lesion to be excised. Usually only two injection sites are necessary. After injecting in one direction, withdraw the needle, rotate it 90 degrees, and inject again. This avoids distortion of the central area around the lesion to be excised.

- Inappropriate administration of anesthetic creates increased pain and anxiety for the patient. Methods for reducing the pain of injection are discussed in Box 4-2.
- For adverse reactions and concerns about toxic doses, see Chapter 5, Local and Topical Anesthetic Complications.

# REDUCTION OF PAIN OF INJECTION

#### **Sodium Bicarbonate**

Injection of local anesthetics can cause pain, which is related to the size of the needle, the rapidity of injection, and the temperature of the anesthetic solution. The acidity of the solution (pH 4.05 to 6.49) also causes a significant burning sensation. This short-lived pain can be reduced by using a small needle, pinching up the skin, injecting slowly, warming the solution (room temperature), and adding 1 mL of sodium bicarbonate solution (7%-10%) to 9 mL of anesthetic. Patients, especially children, will note remarkable improvement in comfort. Infiltration with unbuffered solution has been found to be 2.8 to 5.7 times more painful than infiltration with buffered counterparts. There has been no significant difference detected in the time of onset or duration of anesthesia or in the surface area of skin anesthetized. Occasionally, the addition of bicarbonate can make the solution cloudy, but there are no known adverse effects from this. Other tips to reduce pain with injections are outlined in Box 4-2.

#### Box 4-2. Tips to Reduce Pain with Injections

Use warm solution (room temperature).

Use a small needle (30 gauge if possible).

Inject slowly.

Inject subcutaneously into the adipose tissue (vs.

intradermally, which creates a wheal). It will take longer for subcutaneous injection to take effect but will be less painful.

Warn the patient that the most sensitive areas are fingers, toes, genitals, nose, and perianal area.

Use sodium bicarbonate.

Pinch up and "shake" the skin while the injection is being given.

Use a topical anesthetic (see Chapter 8, Peripheral Nerve Blocks and Field Blocks) before injection.

Use a topical refrigerant to cool the area before injection (e.g., MediFrig, ethyl chloride, Fluori-Methane [15% dichlorodifluoromethane, 85% trichloromonofluoromethane]).

Previously it was indicated that the buffered solution be discarded after 24 hours. Buffered lidocaine is stable for at least 1 week at room temperature. Refrigeration may nearly double that time. Warming the buffered solution to above room temperature may also decrease the discomfort of injection (see Box 4-2).

# **Topical Anesthetics**

Certain clinical situations favor the use of a topical anesthetic (see Chapter 10, Topical Anesthesia). Examples include combative children too large for the papoose board and too young to reason with, and patients with nosebleeds, eye injuries, corneal abrasions, or lesions on mucous membranes that need to be treated with painful modalities, such as liquid nitrogen or electrosurgery. Mucous membranes (i.e., nose, mouth, throat, esophagus, anus, and genitourinary tract) can be anesthetized successfully with many of the local anesthetics by direct topical application. Care must be taken to avoid excess systemic absorption of the topical anesthetic near mucous membranes (see Chapter 5, Local and Topical Anesthetic Complications). On many occasions, the application of topical anesthetic before injection may allow for more accurate administration of injectable anesthetic.

#### **COMPLICATIONS**

Complications of anesthetic administration are listed here, and adverse effects of the drugs themselves are discussed in detail in Chapter 5, Local and Topical Anesthetic Complications. With proper administration, anesthetic complications are quite rare.

- Sensitivity reactions (with esters or multidose vials)
- CNS toxicity: seizure, tinnitus, visual disturbances, altered mental status (if an excess dose is given)
- Cardiovascular toxicity: arrhythmias, bradycardia, hypotension, congestive heart failure exacerbation
- Marked, prolonged vasoconstriction in digit if epinephrine was used (consider rubbing in nitroglycerin ointment for vasodilation)
- Methemoglobinemia
- Infection
- Bleeding
- Tissue/nerve trauma

# POSTPROCEDURE MANAGEMENT AND CONCERNS

Patients should be instructed to watch for redness, pus, swelling, streaking, or increased pain, all of which can be indicative of infection or local sensitivity. When a long-acting agent like bupivacaine is used, warn the patient to exercise caution with activity because the long-acting effect will mask pain and allow enough activity to sustain further injury.

#### **CPT/BILLING CODE**

Administration of local anesthetic is included in the CPT code for individual procedures, and no extra charge can be generated. When anesthetic is administered as part of a joint injection, the CPT code for the joint injection is used. Injection of an anesthetic for diagnostic purposes or a therapeutic nerve block can be billed under a CPT code.

M4450 Introduction/injection of anesthetic (nerve block), diagnostic or therapeutic

# LOCAL AND TOPICAL ANESTHETIC COMPLICATIONS

William L. McDaniel, Jr. • Raymond F. Jarris, Jr.

Many in-office surgical procedures require the use of local or topical anesthetics. *Topical* anesthetics are used more frequently in children for dermatologic procedures and in persons having nasopharyngoscopy and esophagogastroduodenoscopy (EGD). Various mixtures of potent topical medications are also being used more frequently, often under occlusion, to cover large surface areas for many aesthetic procedures. This markedly increases the risk for toxic levels to accumulate.

The primary care physician must have an understanding of the types of complications that may be encountered when using these anesthetics and must be equipped to diagnose and deal with them. For maximum recommended dosages, see Chapter 4, Local Anesthesia.

#### **ALLERGIC REACTIONS**

- Low incidence (<1%).
- Older agents such as procaine and tetracaine (esters) are more likely to cause allergic reactions because they are derivatives of para-aminobenzoic acid, a known allergen.
- There are no reported allergic reactions to lidocaine (an amide) or any other amides.
- In known or suspected local anesthetic allergy, avoid multidose vials of an amide such as lidocaine. Many contain methylparaben preservatives, which have a structure similar to paraaminobenzoic acid.
- True allergic reactions may vary from mild to lifethreatening with anaphylaxis and circulatory collapse. In cases of anaphylaxis
  - Plasma losses may equal 35% of circulating blood volume within minutes.
  - Rapid replacement of volume with colloid and administration of epinephrine are indicated (see Chapter 220, Anaphylaxis).
  - If epinephrine fails, norepinephrine infusion may be lifesaving.

# ALTERNATIVES TO OBTAIN PAIN RELIEF IN ALLERGIC PATIENTS

- Use single-dose vials of lidocaine, which lack preservative.
- Substitute an amide anesthetic for an ester.
- A small local anesthetic effect can be obtained by injecting sterile normal saline into tissue.
- Small lesions (e.g., skin tags) may not require an anesthetic for removal/treatment.
- Dilute 50 mg of diphenhydramine (1 mL from a 50 mg/mL vial) with 4 mL sterile normal saline. Inject 1 to 5 m (10 mg to 50 mg) of this dilute diphenhydramine locally for anesthetic effect.

- Use ice cubes, ethyl chloride spray (Frigiderm), liquid nitrogen (sparingly) to obtain topical anesthesia.
- Hypnosis.

# EFFECTS OF EPINEPHRINE IN LOCAL ANESTHETICS

It has long been an admonition to students, residents, and practicing clinicians that epinephrine should never be used in areas of the body supplied by the fine terminal end arterioles such as the fingers and toes, penis, and nose. Theoretically, the epinephrine could cause prolonged spasm leading to ischemia and even necrosis of the tissue. This effect would be potentially magnified if the vessels were already diseased and narrowed, as occurs in smokers and patients with diabetes, peripheral vascular disease, and similar conditions. Hence, in the past, it was literally seen as substandard care to use epinephrine in these areas, especially when there was potential vascular disease or diminished blood supply.

In 2000, a series of articles began appearing in the literature to refute this "theoretical" adverse effect (see Bibliography). A paper by Denkler published in 2001 reviewed the literature from 1880 through 2000. The conclusion was: "An extensive literature review failed to provide consistent evidence that our current preparations of local anesthesia with epinephrine cause digital necrosis, although not all complications are necessarily reported. However, as with all techniques, caution is necessary to balance the risks of this technique...."

Digits can withstand prolonged periods of ischemia. Successful reimplantations have been reported 42 hours after traumatic amputations.

The usual concentration of epinephrine in local anesthetics is 1:100,000. Studies have been conducted using concentrations of 1:1000 with virtually no adverse consequences.

A multicenter prospective study of 3110 consecutive cases of elective epinephrine use in the fingers and hands (concentration ≤1:100,000) found that "the true incidence of finger infarction in elective low-dose-epinephrine injection into the hand and finger is likely to be remote, particularly with the possible rescue with phentolamine. Phentolamine was not required to reverse the vasoconstriction in any patients" (Lalonde et al, 2005).

"Phentolamine rescue" or reversal of epinephrine is not discussed in this text. Nitroglycerin ointment has also been suggested to reverse any apparent ischemia, however rare (or even possible) this event is.

It would seem acceptable then to use local anesthetics with epinephrine to control bleeding for optimal wound repair and also to prolong needed anesthesia in areas supplied by end arteries. It would appear that an age-old caveat has been disproven. The prudent physician would still observe at-risk patients closely and use epinephrine sparingly.

## **OVERDOSE REACTIONS**

# **Central Nervous System Toxicity**

Local anesthetics reach the central nervous system after slow absorption or by direct intravenous (IV) injection. An inadvertent direct IV injection may create a transient high local central nervous system level of anesthetic, which can cause *seizures*. Most seizures created in this way terminate within minutes, provided the administration of the drug has stopped.

A warning of less serious central nervous system effects may include circumoral numbness, lightheadedness, tinnitus, visual disturbance, muscular twitching, and irrational behavior.

If high serum levels persist, grand mal seizures, apnea, unconsciousness, and death may occur. An alert patient, in most cases, tells the physician before a seizure develops. This would be absent in the case of rapid inadvertent IV injection.

Acidosis and hypercarbia increase the likelihood of central nervous system toxicity. Pulse oximetry monitoring during the procedure may be an invaluable tool to alert the clinician to some of the effects of toxicity.

With serious central nervous system toxicity, stop the offending agent and begin oxygen and support ventilation if needed. Alert patients can be asked to hyperventilate, which lowers the  $PCO_2$  level and raises the seizure threshold. This may temporarily alleviate twitching. Seizures can usually be stopped with IV midazolam (Versed), diazepam (Valium), or lorazepam (Ativan). Lorazepam and diazepam are inconsistently absorbed by the intramuscular (IM) route. Midazolam may be used IM if an IV line is not available. Flumazenil (Romazicon) should be available as an antagonist for benzodiazepines in case of respiratory depression from the drugs.

#### **Cardiovascular Toxicity**

Cardiovascular toxicity can occur with any of the local anesthetic drugs. Local anesthetics prolong conduction through the Purkinje fibers and heart muscle. *Prolongation of PR interval* and *widening of the QRS* may be observed. Higher concentrations decrease heart muscle contractility. *Hypotension*, *respiratory depression*, and *bradycardia* are observed with lidocaine.

If cardiovascular toxic effects are suspected, discontinue or remove the agent when possible. Basic cardiopulmonary resuscitation is the cornerstone of immediate management. Advanced cardiac life support (ACLS) protocols should be initiated as necessary for serious rhythm disturbances. Various studies indicate the cardiotoxicity of bupivacaine is more severe and difficult to treat than that associated with lidocaine. Cardiology and anesthesiology consults should be obtained as soon as available.

## **CATECHOLAMINE REACTIONS**

Catecholamine reactions are rarely associated with administered epinephrine but may be produced as a result of anxiety associated with the administration of a local anesthetic or the initiation of the procedure, or as a result of the initial injury that is being treated. Symptoms may include tachycardia, palpitations, hypertension, apprehension, tremulousness, diaphoresis, tachypnea, pallor, and, on occasion, anginal chest pain. Caution is recommended for patients who have hyperthyroidism, hypertension, or atherosclerotic cardiovascular disease, although these conditions do not contraindicate the judicious use of epinephrine-containing anesthetics. Patients taking monoamine oxidase inhibitors should not receive epinephrine-containing anesthetics. The treatment includes stopping further drug administration, observation of the patient, and administration of alphaor beta-adrenergic antagonists or benzodiazepine agents, if necessary.

#### **VASOVAGAL REACTIONS**

A marked vasovagal reaction may occur if the patient experiences anxiety when an event, such as the sight or sensation of a needle insertion, causes a loss of sympathetic tone and an increased vagal tone. The resulting hypotension and bradycardia may lead to lightheadedness or syncope. If this occurs, the patient should be placed in the supine position with the legs elevated. Ammonia inhalant ("smelling salts") can be tried initially. A 0.3-mL ampule can be crushed and waved in front of the patient's nose. Should this not be effective, give 0.5 mL of atropine (1 mg/mL) IM. This may also be required for significant bradycardia. Practitioners need to be observant and aware that vasovagal syncope can occur even 10 to 15 minutes after a procedure/injection. This has been reported after immunizations also, and such reactions to the Gardasil vaccine have gained significant press.

**EDITOR'S NOTE:** I now include the questions, "How well do you tolerate pain?" (choices: well, okay, poorly) and "Do you have a tendency to faint with needles?" (choices: yes, no) on my intake forms and also on specific procedure questionnaires. If patients answer that they tolerate pain poorly or have a tendency to faint, we routinely give atropine before the surgery/procedure.

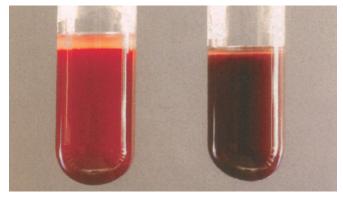

#### **METHEMOGLOBINEMIA**

Methemoglobinemia is a rare but serious complication of topical and local anesthetic agents. It should be clinically suspected and diagnosed if topical or local anesthetics were given. Early diagnosis and treatment can prevent the serious complications of brain damage and death. One must be especially cautious now because, as noted, topical anesthesia is being used more frequently for aesthetic procedures.

The best way to illustrate the point is with a case history. A 27-year-old white man underwent outpatient EGD and developed unexplained cyanosis. During his recovery phase the nurse noted cyanosis, which did not resolve on high-flow oxygen. Vital signs and arterial blood gases were within the normal range. Diagnoses such as pulmonary thromboembolic phenomenon and allergic reactions to meperidine (Demerol) or diazepam (Valium) were considered.

An astute respiratory technician noted that the arterial blood drawn for the arterial blood gases was brown. The diagnosis of methemoglobinemia was suspected and confirmed by discovering a methemoglobin level of 14% (Fig. 5-1).

The patient involved had received Cetacaine spray (a combination of benzocaine, aminobenzoate, and tetracaine) four or five

**Figure 5-1** Normal arterial blood versus methemoglobinemia. Compare arterial whole blood with 1% methemoglobin (*left*) with arterial whole blood with 72% methemoglobin (*right*). Note the characteristic chocolate-brown color of the sample with an elevated methemoglobin level. (From DeBaun MR, Vichinsky E: Hemoglobinopathies. In Kliegman [ed]: Nelson Textbook of Pediatrics, 18th ed. Philadelphia, Saunders, 2007, Fig. 462-6.)

times before the EGD procedure. The endoscopist had requested that the patient swallow the material each time. This spray contains about 14% benzocaine, which was the culprit in this case. The 2007 *Physicians' Desk Reference* lists methemoglobinemia as a rare adverse effect of Cetacaine spray and cautions that care should be used not to exceed a 2-second spray.

Normal hemoglobin contains iron in the ferrous (+2) state. Methemoglobin contains iron that has been oxidized to the abnormal ferric (+3) state. Normal levels of methemoglobin range up to 3%.

Prevent methemoglobinemia by avoiding overdose of benzocaine, prilocaine, and lidocaine. Prilocaine and lidocaine in a eutectic mixture of 2.5% each (EMLA) is considered safe when used as recommended. EMLA is applied topically and is often used in infants and children. One case of methemoglobinemia has been reported with its use over large areas for a long period of time. It is more likely to occur if used under occlusion for large areas for extended times.

Other drugs that can cause methemoglobinemia include sulfonamides, phenytoin (Dilantin), amyl nitrate, dapsone, sodium nitroprusside, quinolones, and nitroglycerin.

The following signs are noted at the various methemoglobin levels:

- Up to 15%: graying of skin
- 15% to 20%: cyanosis becomes apparent and the blood has a chocolate-brown color
- 20% to 50%: weakness, dizziness
- 50% to 70%: arrhythmias, acidosis, convulsions, and coma may
- Over 70%: death and cerebral anoxia may occur

Nitrates, foods, and contaminated well water may predispose to methemoglobinemia and may lower the threshold for local anesthetics.

Treatment varies with the level of methemoglobin present and the condition of the patient. Urgent administration of methylene blue is indicated for symptomatic hypoxia as evidenced by arrhythmias, angina, respiratory distress, seizures, coma, or methemoglobin levels greater than 30%. Methylene blue 1% administered IV slowly over 5 minutes should result in improvement. Adults and children are administered 1 to 2 mg/kg (0.1 to 0.2 mL/kg of 1% solution) or 25 to 50 mg/kg². A second dose can be repeated after an hour if the response was inadequate. Do not exceed 7 mg/kg.

Hyperbaric oxygen therapy may help by increasing the amount of dissolved oxygen in the blood. Consider exchange transfusions in the most severely affected patients. This may require a tertiary center

Successful treatment will be unavailable unless the astute clinician considers the diagnosis of methemoglobinemia (Box 5-1).

# Box 5-1. Factors Suggesting Acquired Methemoglobinemia

A local anesthetic agent was used.

A larger-than-usual dose was needed.

Environmental predisposition present (nitrates) or other predisposing drugs such as sulfonamides, phenytoin (Dilantin), amyl nitrate, dapsone, sodium nitroprusside, quinolones, nitroglycerin, and methamphetamines.

Cyanosis does not respond to usual  $O_2$ .

Arterial blood appears chocolate-brown (usually 15% to 20% levels of methemoglobin present).

Infants and the elderly seem more susceptible to development of methemoglobinemia.

# NITROUS OXIDE SEDATION

Marjon B. Jahromi

Nitrous oxide ( $N_2O$ ) sedation was first used as an anesthetic agent in 1844 and can be considered a safe alternative to intravenous (IV) sedation. Nitrous oxide sedation has a long history of safety in the medical and dental community. It is now used by approximately 95% of pediatric dentists and is growing in popularity in general dental and medical offices. Most U.S.-trained dentists will become proficient in  $N_2O$  sedation as part of their undergraduate dental training. It is not necessary to have extensive experience with IV sedation to be able to perform  $N_2O$  sedation safely. Gaining experience with  $N_2O$  sedation can be achieved by observing an experienced practitioner and performing the sedation under supervision. Alternatively, continuing education courses are available. Practitioners who are not familiar with the technique are encouraged to participate.

Nitrous oxide is a relatively insoluble drug and is a rapidly effective sedative with an onset of effects within 2 to 3 minutes of administration and peak effects within 5 minutes. Dosing can be adjusted easily and rapidly to increase or decrease depth of sedation during the procedure. Recovery time is short because elimination through the lungs occurs as rapidly as absorption.  $N_2O$  is not metabolized in the body to any significant extent and therefore can be used safely on most patients. Patients remain conscious and protective reflexes are intact so there is minimal risk of aspiration or oversedation. In addition,  $N_2O$  does not cause respiratory depression, making it safer than fentanyl, midazolam, or chloral hydrate. Technically, it is easier to perform than IV sedation because there is no need to gain venous access. Nitrous oxide is administered through a face mask or nasal hood that is simply placed on the patient's face.

#### **INDICATIONS**

- Anxious and apprehensive patients undergoing minor office surgical or dental procedures
- Patients needing increased pain reaction threshold
- Patients who are unable to tolerate other sedatives

#### **CONTRAINDICATIONS**

- Pregnancy (first trimester)
- Airway obstruction and severe asthmatic conditions
- Severe psychiatric disorders (N<sub>2</sub>O can cause dreaming and hallucinations)
- Pulmonary hypertension
- Pneumothorax
- Severe cardiac disease
- Hyperthyroidism
- Sickle cell anemia
- Chronic bronchitis/emphysema
- Bowel obstruction

Nitrous oxide should *not* be used to replace local anesthesia but rather as an adjunct to local anesthesia. Nitrous oxide sedation is not a good option to control defiant or erratic behavior.

#### **ADVANTAGES**

- Rapid onset; monitoring time during recovery is brief.
- Good analgesic and amnestic (limited) properties.
- Unlike IV sedation, when nitrous oxide is used alone, a driver is not needed once the patient has recovered. Patients should be monitored for approximately 30 minutes after the use of N<sub>2</sub>O to ensure return to baseline functional status before discharge.
- Patients may resume all normal activities after discharge and are not limited in their activities.

#### **LIMITATIONS**

- Lack of potency
- Expense of equipment
- Training required to become proficient

# **EQUIPMENT**

- Inhalation sedation machine (Fig. 6-1)
- Breathing circuit
- Reservoir bag
- Scavenging system
- Nasal hood or facial mask
- Oxygen and N<sub>2</sub>O supply (N<sub>2</sub>O is stored in compressed form as a liquid in cylinders)
- Pulse oximeter
- Oral pharyngeal airway available

**Figure 6-1** Accutron 4-Cylinder Portable Manifold. (Courtesy of Accutron, Inc., Phoenix, Ariz.)

 Emergency cart with appropriate drugs (consider the Banyan kit; see Chapter 220, Anaphylaxis)

# **PRESEDATION ASSESSMENT AND CONCERNS**

Figure 6-2 shows an anesthesia evaluation form that can be used before and after the procedure.

- A complete medical history should be obtained from the patient. Relevant information includes a history of cardiac or respiratory disease, medications, allergies, prior surgeries and complications from anesthesia, history of tobacco use, and history of substance abuse.
- The oropharynx should be thoroughly evaluated for any abnormalities or evidence of obstruction. A history of sleep apnea may indicate airway abnormalities such as narrow airways and tonsillar hypertrophy. Obesity, especially involving the face and neck, may lead to difficulties in spontaneous ventilation under sedation.
- Nitrous oxide will potentiate drugs that depress the respiratory system.
- The procedure and all possible sensations should be described to the patient in advance. Nitrous oxide can produce a feeling of euphoria, dreaminess, and detachment. It can also cause numbness and tingling of the extremities. It may cause nausea, confusion, and sexual hallucinations in higher doses.

# PREPROCEDURE PATIENT PREPARATION

- An experienced assistant trained in Basic Life Support (BLS) should always be present.
- Patients do not need to fast if nitrous oxide is the sole anesthetic agent. However, if an oral sedative is to be used in combination with nitrous oxide, confirm that the patient has fasted for at least 6 hours for solid foods and nonclear liquids and at least 6 hours for clear liquids.
- Perform a full check of the inhalation sedation machine to ensure that it is safe to use and that it has an adequate supply of gases for completion of the procedure. Nitrous oxide is a compressed liquid at room temperature with a pressure of 745 pounds per square inch. A full E cylinder of N<sub>2</sub>O will have 1590 mL of gas. The pressure indicator in a N<sub>2</sub>O tank will show a constant pressure until only about 20% (400 mL) of N<sub>2</sub>O is left in the cylinder. This is very different from oxygen, which is a nonliquified gas. The pressure indicator in an oxygen tank will indicate a proportional decrease in pressure as the volume of the gas is depleted. Therefore, the pressure indicator of a N<sub>2</sub>O tank cannot be used to estimate the amount of gas remaining in the cylinder.
- The scavenging system should also be checked for proper functioning. It is below the standard of care to operate a N<sub>2</sub>O unit without a scavenging apparatus.
- The health care practitioner should have all the necessary equipment and be prepared to handle all medical emergencies in the event the patient should reach a deeper level of sedation than initially planned. Although not required, a pretracheal stethoscope is an excellent method to monitor the patient's respirations and heart sounds. This may prevent the patient from becoming oversedated and losing consciousness. The conventional or newer wireless pretracheal stethoscope can be easily obtained by any health care practitioner (Figs. 6-3 and 6-4).

#### **DOCUMENTATION**

- Informed consent should be obtained for both the planned procedure and the N<sub>2</sub>O sedation. All written and verbal instructions, including consent with risks, benefits, alternatives, and contraindications, should be documented.
- The patient's vital signs, including blood pressure, heart rate, and oxygen saturation by pulse oximetry, should be recorded at regular intervals throughout the procedure and during recovery.

 Any standardized anesthesia form can be used for documentation (Fig. 6-5). Alternatively, vitals, level of sedation, and concentration of N<sub>2</sub>O being administered can simply be recorded at 5-minute intervals (also see Chapter 2, Procedural Sedation [Sedation and Analgesia]).

#### **TECHNIQUE**

- 1. Always have a BLS-trained assistant present.
- Begin the inhalation sedation session with a full check of the inhalation sedation machine to ensure that it is safe to use and that it has an adequate supply of gases to allow the procedure to be completed. Also check the scavenging system for proper functioning.
- 3. Once the presedation check has been completed, position the patient properly for the procedure to be performed. Obtain and record baseline vital signs, including continuous pulse oximetry. A pretracheal stethoscope may also be placed at the lower end of the trachea and midline to the neck for additional monitoring of respirations.
- 4. Place a nasal hood or facial mask on the patient's face. The nasal hood should fit snugly around the patient's nose to minimize any leakage of gas. Nasal hoods come in a variety of sizes and may be scented for optimal patient comfort. Most nasal hoods manufactured now are also latex free.
- 5. Introduce 100% oxygen only. The initial gas flow rate should be set to 6 L/min. The patient should be instructed to take deep breaths through his or her nose. Adjust the flow rate so that the reservoir bag can be seen moving during each breath without completely emptying. If the reservoir bag completely empties, the flow rate should be increased until about two thirds of the bag empties with each patient breath.
- 6. Once the flow rate has been adjusted to the proper level, introduce the N<sub>2</sub>O. Patient tolerance and N<sub>2</sub>O requirement vary significantly for each person. It is important to titrate the dose slowly to prevent oversedation. Oversedation should be avoided because it can result in unpleasant feelings for the patient. Initially, 10% N<sub>2</sub>O is introduced and the patient is allowed to breathe this mixture for 1 minute. The O<sub>2</sub> level should also be adjusted to maintain the constant flow rate that was previously established. Some inhalation sedation machines will also automatically decrease the O<sub>2</sub> flow as the N<sub>2</sub>O flow is increased.
- 7. If this dose provides adequate sedation, the operative or dental procedure can begin. Signs of adequate sedation include a reduction in anxiety, increased relaxation, slowing of the blink reflex, decreased response to painful stimuli, and general decrease in movements.
- 8. If this level of sedation is not sufficient, provide an additional  $10\%~N_2O$  and allow the patient to breathe the mixture for 1 minute before reassessment. This cycle can be repeated to a maximum mixture of  $70\%~N_2O$ :30%  $O_2$ . Document the level and length of  $N_2O$  administered in the patient's medical chart.
  - **NOTE:** Minimum dose is  $10\% N_2O$ :  $90\% O_2$ . Maximum concentration is  $70\% N_2O$ :  $30\% O_2$ . Average maintenance dose is typically between  $20\% N_2O$ :  $80\% O_2$  and  $40\% N_2O$ :  $60\% O_2$ . Almost all ambulatory  $N_2O/O_2$  delivery systems have an oxygen fail-safe mechanism that prevents  $N_2O$  from being administered unless there is adequate  $O_2$  flowing to the system. Therefore, it is not possible to administer  $100\% N_2O$ .
- 9. Immediately reduce the N<sub>2</sub>O concentration with the first sign of oversedation. Signs of oversedation include agitation, sweating, nausea, vomiting, lack of cooperation, diaphoresis, inability to keep eyes open, decreased response to questions, and loss of consciousness. The patient is also at risk for silent aspiration if vomit reaches the epiglottis. Patients may also complain of unpleasant feelings such as intense tingling or detachment from

- reality. It is imperative that the health care provider constantly assess the level of sedation because changes in patient comfort
- 10. With lengthy administration (>30 minutes), reduce the N<sub>2</sub>O concentration. The duration of exposure to an anesthetic can have an effect on recovery time. Accumulation of anesthetic in tissues such as muscle, skin, and fat increases with continuous inhalation and can delay recovery time. This is especially true of the more soluble anesthetics, but it can also occur to some degree with low-solubility anesthetics.
- 11. Once the procedure is complete, the N<sub>2</sub>O can be reduced and the patient returned to breathing 100% O2 for 3 to 5 minutes. This should be achieved by reducing the inspired concentration of N<sub>2</sub>O by 20% per minute until it is reduced to zero.

# **COMPLICATIONS**

- Oversedation or prolonged administration can lead to agitation, sweating, nausea, vomiting, feelings of detachment, confusion, hallucinations, and unconsciousness.
- Nitrous oxide can cause myocardial and respiratory depression in high doses (>70%).
- Chronic effects of N2O exposure can include bone marrow suppression, mainly through inhibiting enzymes that depend on vitamin B<sub>12</sub>. As a result, myelin formation and DNA synthesis may be affected. Megaloblastic anemia, pernicious anemia, peripheral neuropathies, and an increased incidence of miscarriages can also occur as a result of chronic N<sub>2</sub>O use. Central nervous system degeneration is common among those who abuse N<sub>2</sub>O. Scavenging of waste gases is therefore crucial to protect office staff. The National Institute for Occupational Safety and

Figure 6-4 Wireless pretracheal stethoscope. (Courtesy of Sedation Resource, Inc., Lone Oak, Tex.)

Health (NIOSH) recommends limiting the room concentration of  $N_2O$  to 25 ppm.

# POSTPROCEDURE MANAGEMENT AND CONCERNS

- Monitoring of vital signs along with pulse oximetry should be continued during recovery.
- The patient should breathe 100% O<sub>2</sub> for 3 to 5 minutes after the procedure to prevent diffusion hypoxia.
- Diffusion hypoxia is a condition caused by the rapid release of N<sub>2</sub>O from the blood. Because N<sub>2</sub>O is insoluble, it leaves the bloodstream rapidly once the inspired concentration is reduced. If the inspired concentration of N2O is high, then a large amount of gas will quickly emerge from solution into the alveoli, displacing O<sub>2</sub>. This mechanism requires large volumes of N<sub>2</sub>O to be released from the alveoli, which usually occurs during the first 5 minutes of recovery. Room air does not have an O2 concentration high enough to compensate for the high N2O concentration released from the alveoli after the procedure. Thus, hypoxia can occur if supplemental O<sub>2</sub> is not given and if the patient is not allowed to breathe 100% O<sub>2</sub> for 3 to 5 minutes after the discontinuation of N<sub>2</sub>O sedation.
- Symptoms of diffusion hypoxia include disorientation, nausea, and severe headache.
- All written and verbal instructions that were given should be documented.
- Postoperative instructions are more relevant to the actual procedure that was performed; therefore there are no specific postoperative instructions for N<sub>2</sub>O sedation.
- The patient should be alert and oriented before discharge. If nitrous oxide was the only sedation used, the patient may drive himself or herself home. However, if an oral sedative was used in combination with nitrous oxide, a driver is required to take the patient home.

## **CPT/BILLING CODES**

99141 Sedation with or without analgesia (conscious sedation); intravenous, intramuscular or inhalation.

NOTE: 94760-94762 may not be reported in addition to 99141.

# PEDIATRIC SEDATION AND ANALGESIA

Paul W. Davis

Over the past decade, various professional medical societies and hospital associations have readdressed the challenging issue of sedation and pain control in children with the goal of developing multidisciplinary guidelines for what constitutes acceptable and satisfactory care. These societies have included the American Academy of Pediatrics (AAP), the American Society of Anesthesiologists (ASA), and the Joint Commission for Accreditation of Healthcare Organizations (formerly, JCAHO). Their recommendations not only rely heavily on expert opinion and consensus but openly advise that all pediatric sedation be performed under the direction of pediatric subspecialists. We respectfully disagree with the assertion that only pediatricians and anesthesiologists can safely and effectively administer these medications.

The administration of medications for analgesia and moderate or deep sedation was previously termed *conscious sedation*. Because these medications actually do alter a patient's level of consciousness and perception of pain, however, the phrase is inaccurate and is now rarely used.

# HISTORICAL PERSPECTIVE ON UNDERTREATMENT OF PAIN

Historically, the management of pain and anxiety in the pediatric population outside of the operating room has been inadequate. Indeed, several studies have suggested that inattention to painful conditions may be more prevalent for pediatric procedural care delivered outside of children's hospitals. Nevertheless, any physician who has performed even minor procedures for infants and children appreciates the value of being able to safely and predictably sedate them. Aside from the psychological shock and trauma imposed on infants and children because of a limited understanding of the purpose for a procedure, developmental responses to pain vary by age and can thwart the most well-meaning clinician's efforts to complete a needed procedure.

At least six factors have been identified as contributing to the undertreatment of pain and anxiety in the pediatric population: (1) lack of familiarity with the use of sedative agents; (2) the erroneous conception that newborns and infants do not feel pain; (3) the incorrect belief that children have a very short-term recollection of painful events; (4) the fear of adverse effects of sedatives and analgesics; (5) the fear of masking the symptoms and signs of progressive injury or complications of treatment; and (6) the overarching underestimation of pediatric pain because of the young patient's inability to describe or quantify it.

# DEVELOPMENTAL DIFFERENCES IN THE PERCEPTION OF PAIN

Although the physiologic response to pain is similar in adults and children, recent studies involving young children and fetuses suggest

that they may actually experience a heightened perception of pain. A child's perception of pain and clinical reaction to painful stimuli are influenced by several factors, including age, cognitive level, past experiences, extent of control over the situation, parental responses, and perceived cause and expected duration of the painful experience.

The plan for treatment should account for the differences in the pain response at different stages of development:

- Less than 6 months—Anticipatory fear is not present and the infant reflects the level of anxiety of the parent. Withdrawal, facial grimacing, thrashing, and brief crying are typical expressions of pain.
- 6 to 18 months—Anticipatory reactions begin to appear in response to fear of a suspected painful experience (e.g., withdrawal of a limb at the sight of a needle).
- 18 to 24 months—Children begin to use words like "boo boo" and "hurt" in response to expected painful stimuli.
- 3 years—Children are still unable to understand the reason for pain but are able to localize pain and identify its cause. They are more capable of reliably assessing the pain they feel. Their tolerance for a painful procedure is improved by allowing them some sense of control over certain aspects of the situation (e.g., when it will be performed or how they are positioned).
- 5 to 7 years—Continued improvements in understanding of purpose and necessity of painful stimuli occur at this age with consequent improved cooperation.
- 8 to 12 years—Comprehension of the whole process continues to grow with improved understanding/localization of internal pain.
- Adolescence—Children are adept at qualifying and quantifying pain and they develop coping strategies similar to those of adults that help to diminish the perception of pain.

This chapter addresses the current breadth of effective pharmacologic and nonpharmacologic methods to alleviate both pain and anxiety in the pediatric patient before surgical operations and other procedures.

## Nonpharmacologic Techniques

Needlesticks represent the most common source for iatrogenic procedural pain worldwide. From simple immunizations to venipuncture for laboratory studies to anesthetic injection before dermatologic procedures, laceration repair, and orthopedic reductions, needle pain is ubiquitous. In addition, more and more children are undergoing nonmedical procedures like body piercings and tattooing (or removal of tattoos).

Untreated pain in the pediatric population has been studied extensively and does have long-term emotional and medical outcomes that are lifelong. Children now receive more than 20 needlesticks for immunizations before they are 2 years of age and many

develop needle phobia because only 1 in 9 is done with any kind of pain control. Adolescents subsequently avoid needed medical treatment, 16% to 75% of adults surveyed refuse to donate blood, patients with human immunodeficiency virus infection delay needed blood tests and continue to infect sexual partners, and geriatric patients refuse influenza and pneumococcal vaccines owing to fear of needle pain.

Physicians who perform neonatal elective circumcisions know first-hand the benefits associated with the oral administration of "sugar water." The analgesic effect and safety of sucrose for procedural pain both with and without the use of a pacifier (non-nutritive sucking) in neonates have been clearly demonstrated. Effectiveness in older patients is less clear, but it is easy to administer and there are no known adverse effects. Aspiration has not been a reported complication. The influence of age, intercurrent illness, type of procedure, and location of procedure is unclear at this time.

The simplest and most common nonpharmacologic method used with children is voluntary and external distraction. Giving the child and parent verbal reassurance by providing them with information about the procedure before it is started may help allay anxiety but might also make it worse. Hypnosis has been used to help direct children's focus away from the procedure. Young patients can be taught to repeat positive statements to themselves to distract them and relieve anxiety. These behavioral and cognitive approaches represent useful adjuncts that are frequently overlooked because of perceived time constraints in a busy office or emergency department. Distraction techniques include counting or saying the "ABCs," music and videotapes, bubble blowing, spinning pinwheels, using party blowers, playing "I Spy" games, and the use of "medical play" as employed by child life programs. Behavioral treatments include the techniques of desensitization (the gradual, increasing exposure to a procedure over time), positive reinforcement (rewards and positive statements during or after a procedure), and relaxation technique (the use of breathing, imagery, and self-hypnosis to decrease anxiety). Although all of these techniques have been shown to be very effective, they need props, take time, and require trained personnel.

The dorsal column of the spinal cord forms a common final pathway for several kinds of afferent neurologic stimuli, including pain, position, temperature sensation, and vibration. By applying the "gate theory" and stimulating nerve fibers with either cold or vibration, the sensation of sharp pain can be decreased or eliminated by interfering with its transmission because of the other impulses. The use of cold water or ice and the application of vibrating massagers represent effective ways of ameliorating pain. Cold sprays (e.g., Painease; Gebauer, Cleveland) have been widely used but the research into their efficacy in children has been equivocal at best. A device that uses vibration is currently under investigation (Buzzy; MMJ Labs, Atlanta). Pediatric dentists frequently use tactile vibration using their opposite hand in the delivery of oral anesthesia, with great success.

## **TOPICAL ANALGESICS FOR CHILDREN**

Also see Chapter 10, Topical Anesthesia.

Ease of administration with minimal trauma for the child and parent would make these the medications of choice for a large variety of procedures. The reality has never lived up to the promise, however.

The topical agent most commonly used for laceration repair in children is LET (a combination of lidocaine, epinephrine, and tetracaine) with an onset of action of 20 minutes. EMLA cream is a eutectic mixture of lidocaine and prilocaine but often requires application approximately 1 hour before the procedure, limiting its usefulness. LMX 4 is a nonprescription 4% liposomal lidocaine preparation that is also effective as a topical anesthetic agent.

Recently, Zingo (Anesiva, Inc., South San Francisco) has been approved by the U.S. Food and Drug Administration (FDA) for use on intact skin to provide topical local analgesia before venipuncture

or peripheral intravenous cannulation in children 3 to 18 years of age. This needle-free product has a novel delivery system using pressurized gas jets that deliver lidocaine hydrochloride monohydrate, 0.5 mg, directly through the epidermis and into the dermis. Zingo comes as a ready-to-use, sterile, single-use, disposable, needle-free delivery system. The product consists of a drug reservoir cassette filled with 0.5 mg lidocaine powder (particle size of 40  $\mu m$ ), a pressurized helium gas cylinder, and a safety interlock. The safety interlock prevents premature triggering of the device. Once Zingo is pressed against the skin, the interlock is released, allowing the button to be depressed to deliver the anesthetic. Triggering the device results in a sound not unlike the popping of a balloon. Because the price of this single-use product is between \$20 and \$25, its use can increase the cost of venipuncture considerably. Although use can be repeated, if necessary, at a different site (a frequent requirement when attempting to place an intravenous catheter in dehydrated children), repeated use at the same site is not recommended and the clinician needs to pay heed to the total dosage of anesthetic administered to avoid toxicity.

Zingo provides local dermal analgesia within 1 to 3 minutes of application and analgesia diminishes within 10 minutes of treatment. Most adverse reactions were application site—related and included bruising, burning, pain, contusion, and hemorrhage. These occurred in 4% of pediatric patients. The most common systemic adverse reactions were nausea (2%) and vomiting (1%). Erythema, edema, pruritus, and petechiae occurred in approximately half of all patients and were brief and self-limited.

# PHARMACOLOGIC AGENTS FOR SEDATION AND ANALGESIA

The ideal pediatric agent for procedural sedation would have certain characteristics. First, it would be both 100% safe as well as completely effective for the full range of desired properties—amnesia, analgesia, anxiolysis, motor control, and sedation. It would have rapid onset, fast recovery, a predictable duration of action, and would be completely reversible. In addition, it would be easy to titrate and painless to inject, provide choices for administration route, and be easy to administer. Finally, such an ideal agent would be entirely free of adverse effects and complications.

Needless to say, this ideal pediatric sedative agent has yet to be discovered. A wide range of approved short-acting agents are currently available for use as sedative—hypnotics or analgesics in infants and children. Each of these agents offers advantages in select situations and for specific patients. Procedures that are not painful but require patients to cease moving can be performed with sedation alone. Painful procedures, however, require both sedation and analgesia.

The American College of Emergency Physicians has developed an evidence-based clinical policy for the use of pharmacologic agents for sedation and analgesia in children. This policy focuses on etomidate, fentanyl/midazolam, ketamine, methohexital, pentobarbital, and propofol. The specific uses, recommendations, and cautions for both these and other agents are addressed in the following section. Specific indications and contraindications are addressed individually for each medication. The important characteristics of selected agents are summarized in Table 7-1 for easy reference.

## **Sedative-Hypnotic Agents**

These medications provide anxiolysis, control of movement, sedation, and often amnesia for the painful event, but do not provide analgesia.

## "Lytic Cocktail"

This time-honored mixture is addressed briefly here for historical reasons and because many older primary care physicians have used this regimen extensively in the past with great success. The "lytic

TABLE 7-1 Su	mmary of Importan	t Characteristics of Selected Agents	s
Characteristic	Chloral Hydrate	Fentanyl	Ketamine
Dose and route	Oral and rectal: 25–100 mg/kg up to 1 g/dose infants and 2 g/dose older children	IV: 0.5–2 μg/kg/dose Titrate q3min to desired effect Suggested max: 3 μg/kg	IV: 0.25–2 mg/kg; start with 0.25–0.5 mg/kg and titrate to effect q3–5min (suggested max: 2 mg/kg). Combine with atropine 0.01–0.02 mg/kg IV IM: I-4 mg/kg (suggested max: 4 mg/kg). Combine with atropine 0.02 mg/kg IM Oral: 4–6 mg/kg (suggested max: 6 mg/kg). Combine with atropine 0.02–0.03 mg/kg Rectal: Same as oral
Onset of action/ time to peak effect	Onset 15–30 min Peak effect 30–60 min	Onset I min Peak effect 2–3 min	IV: onset <1 min, peak several minutes IM: Onset 2–5 min, peak 20 min (dose dependent) Oral and rectal: Onset >5 min, peak 30 min (dose dependent)
Duration of action	60 min—residual sedation may last longer in neonates and toddlers	30–45 min	IV: 15 min IM: 30–120 min Oral and rectal: Onset >5 min, peak 30 min (dose dependent)
Adverse reactions	Respiratory depression Airway obstruction	Respiratory depression Bradycardia Dysphoria Delirium Nausea Vomiting Pruritus Urinary retention Smooth muscle spasm Hypotension Allergic reaction Chest wall/glottic rigidity	Laryngospasm Rare respiratory depression Decreased response to hypercarbia Stimulation of salivary and tracheobronchial secretions Mild to moderate increase in blood pressure, heart rate, and cardiac output Emergence phenomena (hallucinations, nightmares, severe agitation) Paradoxical hypotension Skeletal muscle hypotension Skeletal muscle hypotension Skeletal muscle hypotension Random movements of head or extremities Elevated intracranial and intraocular pressure Nystagmus Vomiting Transient erythematous rash Loss of protective reflexes/aspiration Allergic reaction
Drug Interactions	Coadministration of other sedatives or narcotics increases risk of respiratory complications Can alter warfarin metabolism	Coadministration of other respiratory depressants like benzodiazepines increases the risk of respiratory depression	Half-life may be prolonged if given with other agents metabolized in the liver Coadministration with benzodiazepines or opiates may decrease the occurrence of hallucinations but may also prolong recovery
Contraindications	Repeated dosing in neonates Patients with significant liver or renal disease Patients with cardiac arrhythmias Patients with porphyria	Known allergy or prior serious adverse event	Presence of URI increases risk of laryngospasm to 9% Presence of potential head injury Known increased intracranial pressure Open globe injury Hypertensive disease Coronary artery disease Psychosis Prior adverse reaction to ketamine
Comments	Dose should be decreased in high- risk or debilitated patients Most effective in children under 4 yrs of age	Slow infusions and lower doses decrease the risk of chest wall rigidity Chest wall and glottic rigidity can be reversed with succinylcholine or naloxone Dose should be decreased in high-risk or debilitated patients Respiratory depressant effects may last longer than opioid effects Use with caution in patients at risk for cholelithiasis Delayed clearance in patients with hepatic disease	Causes dissociative reaction (a "trance-like" state) Provides amnesia, analgesia, immobilization, and sedation All-or-none sedation—no sedation continuum Especially useful for young children (lower incidence of emergence phenomena)
Antagonist	None	Naloxone—IV/IM/SQ at 10-100 mcg/kg Adolescent dose: 0.1-0.8 mg Titrate slowly to patient response waiting 2-3 min between doses	None

BP, blood pressure; CHF, congestive heart failure; CI, contraindicated; CNS, central nervous system; CO, cardiac output; HR, heart rate; IM, intramuscular; IV, intravenous; Min, minutes; Mo, months; Sec, seconds; SQ, subcutaneous; SVR, systemic vascular resistance; URI, upper respiratory infection; Yr, years.

cocktail" consists of chlorpromazine (Thorazine), promethazine (Phenergan), and meperidine (Demerol) and is given intramuscularly according to the weight of the child: chlorpromazine, 0.5 mg/kg; promethazine, 0.5 mg/kg; and meperidine, 0.7 mg/kg. It is not recommended because (1) the physician must deal with the side effects of three medications instead of one (polypharmacy); and (2) its effect can be erratic and unpredictable.

#### Benzodiazepines (Midazolam)

Benzodiazepines provide sedation, anxiolysis, and amnesia, but do not provide analgesia. There are several reasons why midazolam (Versed) is the most commonly used agent in this category and the clear drug of choice for pediatric procedures requiring merely sedation and anxiolysis. Midazolam has a rapid onset of action, short duration of action, and rapid recovery time. Although patients may not appear sedated when it is used as a single agent, they become more relaxed and cooperative, and there is the frequent (but not universal) benefit of a marked amnestic response for the event. Controversy exists as to whether this marked amnestic response actually blocks "intrinsic memory"—that is, although patients may not consciously recall the painful incident, the traumatic event is still recorded in the brain at the subconscious level. For this reason, it is advisable to coadminister an appropriate analgesic agent for painful procedures.

Midazolam offers great flexibility in route of delivery because it can be administered by the *oral*, *intranasal*, *sublingual*, *rectal*, *intramuscular* (*IM*), *or intravenous* (*IV*) *route*. Its efficacy is well established. When used as a single agent (i.e., not combined with an opiate, ketamine, or droperidol), however, it is inferior to other regimens or single agents, and patients may appear to be wide awake.

Recommended dosages vary depending on route of administration. Oral midazolam is given at doses of 0.5 to 1 mg/kg and results in the onset of mellowness at 15 to 30 minutes. Intranasal midazolam at recommended dosages of 0.3 to 0.5 mg/kg has a more rapid onset of action at 5 to 15 minutes, duration of action of 15 to 20 minutes, and some effects lingering for up to several hours. The solution is drawn up into a tuberculin syringe, the needle removed, and the drug then instilled into the child's nares with the child supine or the headed tilted back. Recommended rectal doses of midazolam are 0.45 to 1 mg/kg, with efficacy reported variably from 62% to 93% for laceration repair. Agitation (reported in up to 17%) has been the major drawback of this route of administration. The recommended IV dose of midazolam is 0.05 to 0.1 mg/kg and the IM dose is 0.05 to 0.15 mg/kg; time to peak effect is 3 to 5 minutes for the IV route and variable for the IM route. Duration of action is 2 to 4 hours.

Adverse effects are uncommon and include the atypical effects of paradoxical agitation and euphoria after administration or an emergence reaction when given IV (1.4%) or orally (6%). Hypotension and respiratory depression are rare but can occur, especially if a narcotic agent is coadministered. The antagonist flumazenil (Romazicon) at a dose of 0.002 to 0.02 mg/kg IV can be given to reverse the effects of midazolam, but patients will require a longer period of observation in recovery (2 hours is commonly recommended) because this agent may have a shorter duration of action than the benzodiazepine, with consequent recurrence of sedation or respiratory depression.

#### Chloral Hydrate

Not very many years ago, chloral hydrate was considered the mainstay of safe, effective pediatric sedation. Although it has a wide margin of safety, chloral hydrate is *primarily used to sedate children* younger than 3 years of age for diagnostic imaging because its effects on older children are unreliable. It can be administered *orally* or rectally at a dose of 25 to 100 mg/kg up to 1 g/dose for infants and 2 g/dose for older children. Chloral hydrate has an unpleasant smell and taste, making it difficult to entice a child to take much of it orally. Peak action occurs at 60 minutes, making it much less useful than other agents in the emergency setting. Its duration of

action is quite variable, with sedation lasting from 1 to 4 hours after administration.

Adverse effects include prolonged sedation, paradoxical agitation, and coma, but airway obstruction and respiratory depression can occur and there is no consistent dose below which complications do not occur; deaths have been reported. In one published series, adverse events were reported in 33% of children who received chloral hydrate either alone or in combination with other sedatives. This relatively high rate of complications contrasts markedly with the widespread perception of its safety. There is no reversal agent for chloral hydrate and its use is contraindicated in patients with cardiac, hepatic, and renal disease as well as porphyria. In addition, its sedative effects can be difficult to predict. In the past, this agent was frequently used in unmonitored settings. In light of the difficulty in predicting its sedative effects and the attendant risks with its use, it is imperative that procedural sedation protocols for monitoring patients during and after administration of this agent be strictly followed.

# Barbiturates (Methohexital, Thiopental, and Pentobarbital)

Barbiturates are *primarily used for sedating children younger than 3 years* of age to perform diagnostic imaging. They are relatively safe but are contraindicated in patients with porphyria. Major side effects include respiratory depression with apnea and hypotension, both of which are more common when barbiturates are used in combination with opiates or benzodiazepines.

Methohexital (Brevital) is an ultra–short-acting agent with an onset of action of 30 to 60 seconds and duration of effect of 5 to 10 minutes. It can be administered intravenously at a dose of 1 to 1.5 mg/kg to children 3 to 12 years of age. It is contraindicated in children with temporal lobe epilepsy because it can cause seizures in this subgroup.

Thiopental (Pentothal) is also a short-acting barbiturate with an onset of action of 30 to 60 seconds but a slightly longer duration of effect of 15 minutes. It is generally given rectally to children at a dosage of 5 to 10 mg/kg and has the notable side effect of decreasing intracranial pressure. It is therefore particularly useful in patients for whom increased intracranial pressure is a concern.

Pentobarbital (Nembutal) is a very useful barbiturate sedative for longer radiologic procedures like magnetic resonance imaging and positron emission tomography scans. It has an onset of action of 3 to 5 minutes when given IV and a duration of effect of 30 to 45 minutes. For children and infants more than 6 months of age, it can be given intravenously at a dosage of 1 to 3 mg/kg and titrated every 3 to 5 minutes to a maximum dosage of 100 mg, or intramuscularly at a dosage of 2 to 6 mg/kg to a maximum dosage of 100 mg.

#### **Etomidate**

Etomidate is an ultra–short-acting imidazole (nonbarbiturate) hypnotic agent with no analgesic properties. Although studies have been published supporting its safety and efficacy in children, the FDA does not currently recommend its use in children younger than 10 years of age.

Its consideration as a potential sedative for children stems from its use in the emergency department for both adults and children as an induction agent in rapid-sequence intubation. After the administration of the *recommended dose* of 0.3 mg/kg IV, etomidate has a rapid onset of action of 5 to 30 seconds and a duration effect of only 5 to 15 minutes. It has the major advantage of decreasing intracranial pressure, like thiopental, and not adversely affecting hemodynamic stability. Reported *adverse effects* include myoclonus (22% of children receiving it in one study) and oxygen desaturation. When given with fentanyl for analgesia, its safety and efficacy compare favorably with midazolam and fentanyl. Compared with pentobarbital for pediatric sedation before diagnostic imaging, etomidate provided a shorter duration of sedation, greater overall efficacy, fewer failures, and fewer adverse effects.

#### Propofol

Propofol is a nonopioid, nonbarbiturate sedative-hypnotic agent that produces deep sedation almost immediately after IV administration (the one arm-brain circulation time is approximately 40 seconds). It has no analgesic properties but does produce a modest amnestic effect (although weaker than that of midazolam) and is affectionately known as "oil of amnesia," although this term would be more aptly applied to midazolam. Propofol has been used extensively by anesthesiologists and pediatric intensivists as either an induction agent for general anesthesia or as a sedative in the pediatric intensive care unit for patients requiring mechanical ventilation or other uncomfortable procedures. It acts as a direct muscle relaxant and has both antiemetic and euphoric properties. It has no adverse effects on hepatic or renal function. Propofol does not increase either the intraocular pressure or intracranial pressure. When given in conjunction with an opioid analgesic agent, it provides very effective analgesia and sedation for painful procedures. It also has the benefit of an extremely short recovery time of 5 to 15 minutes. Even if deep sedation inadvertently drifts into general anesthesia, with the attendant need for assisted ventilation, the patient is likely to awaken within a few minutes after cessation of the IV infusion. Nevertheless, controversy remains intense regarding the use of propofol outside of the operating room or intensive care unit, or by nonanesthesiologists.

The recommended induction dosage for children 3 to 16 years of age is 2.5 to 3.5 mg/kg, administered IV over 20 to 30 seconds. A lower dosage should be administered in children with an ASA classification of III or IV. Intravenous infusion should follow using a rate of 200 to 300  $\mu$ g/kg/minute for children 2 months to 16 years of age, decreasing the dose to 125 to 150  $\mu$ g/kg/min after the infusion has been running 30 minutes or longer. Higher infusion rates may be required for children younger than 5 years of age.

Adverse effects noted with propofol include apnea, hypotension, bacterial contamination of the lipid emulsion, and pain at the site of injection (must be administered with lidocaine). Propofol decreases the systemic vascular resistance by an estimated 15% and cardiac output by more than 10%. Hypotension has been reported to occur between 17% and 92% of the time. Respiratory depression results in decreased tidal volume and unpredictable apnea. Oxygen desaturation has been reported in 5% of cases and simple airway interventions were required in 3% of patients; increased oxygen concentration sufficed for almost all other patients. The need for endotracheal intubation has been reported in only 0.03% of patients. It is difficult to titrate this drug because of both its potency and its rapid onset of action and time to peak effect. Indeed, this may be the root cause for the frequency with which this agent results in a deeper level of sedation than intended.

In several observational studies, propofol sedation has been reported to be both safe and effective when performed by trained emergency department personnel as long as established practice guidelines and hospital protocols are followed strictly. Because it is considered a general anesthetic agent, a second qualified and credentialed provider (i.e., not the physician performing the procedure) should be present to administer and monitor the patient throughout the procedure until the patient is fully awake. The patient should be carefully monitored with pulse oximetry as well as capnography and physical monitoring of spontaneous respiratory effort.

Propofol is relatively *contraindicated* in patients with a known allergy to eggs or soybeans because current formulations of propofol contain soybean oil, egg lecithin, and egg yolk phospholipids. The generic form contains sulfites, so the brand name Diprivan must be used for sulfite-allergic patients.

Propofol can be coadministered with opioid analgesics or midazolam, but the initiating and maintenance dosage of propofol will likely need to be decreased. The likelihood of sedation events and complications is increased with the coadministration of narcotics. Adverse events are also more likely when propofol is used for sedation in patients with an ASA classification of III or higher.

# **Other Agents**

#### Ketamine

Ketamine is a phencyclidine derivative and is unique among the sedative–hypnotic and analgesic agents in that it is a "dissociative sedative." It actually produces a trancelike state and provides amnesia, analgesia, immobilization, and sedation. It is therefore an ideal agent for use in young children, often being used as a single agent, resulting in an enhanced safety profile. Unlike other tranquilizers, there is no "sedation continuum" (i.e., the sedative effect is either present or absent). Ketamine is often used in young children for brief, painful procedures like fracture reduction and laceration repair.

Not only is ketamine very effective when used according to practice guidelines, it is very safe. Patients almost always retain protective airway reflexes, intact upper airway muscular tone, and spontaneous breathing. It can be administered orally (4 to 6 mg/kg), rectally (4 to 6 mg/kg), IM (1 to 4 mg/kg), or IV (0.25 to 2 mg/kg). IV doses can be titrated to effect every 3 to 5 minutes starting with 0.25 to 0.5 mg/kg. Onset of action is less than 1 minute with IV use, with maximal effect noted at approximately 3 to 4 minutes. Onset of action is 2 to 5 minutes with IM use, with maximal effect noted at 20 minutes. Oral and rectal use results in an even slower onset of action, with peak effect at 30 minutes. With IV use the duration of effect is short, 15 minutes, but recovery times are much longer (30 to 120 minutes) and less predictable for oral, IM, and rectal use.

Side effects of ketamine include both vomiting and increased salivation. The latter can be controlled by preadministration of either atropine or glycopyrrolate. Laryngospasm occurs very rarely and can be managed by positive-pressure bag-mask ventilation. Ketamine is most known for the frequent occurrence of unpleasant hallucinations and nightmares as well as severe agitation during emergence from sedation. These emergence phenomena are much more common in patients older than 15 years of age and extremely rare in younger children. Coadministration of midazolam has been proposed to minimize this adverse effect, but to date there are no convincing large studies to support this. Although midazolam also decreases the incidence of vomiting with ketamine, it also results in a four- to fivefold increase in the incidence of oxygen desaturation. Still, ketamine with midazolam has been associated with fewer adverse events compared with ketamine combined with fentanyl or propofol, especially in children younger than 10 years of age.

Unfortunately, ketamine has *many contraindications*, including age less than 3 months, airway instability, cardiovascular or pulmonary diseases including bronchospasm, glaucoma or eye injury, increased intracranial pressure or head injury, porphyria, thyroid disease, and psychosis.

#### Nitrous Oxide

Also see Chapter 6, Nitrous Oxide Sedation.

Inhaled nitrous oxide provides amnesia, mild analgesia, anxiolysis, and sedation when mixed in a 1:1 ratio with oxygen and administered through a demand-valve mask. This system requires patient cooperation, so this method of sedation is generally reserved for children older than 4 years of age.

At the concentrations usually used for sedation and analgesia, nitrous oxide use preserves protective airway reflexes, normal blood pressure and pulse, and spontaneous respirations. It has an excellent safety profile, and *adverse effects* are typically mild, including nausea, vomiting, and occasional dysphoria. It can be used alone or in combination with other sedatives and analgesics and it has a proven track record of efficacy for a variety of painful procedures. *Contraindications* include pregnancy, vomiting, and the presence of known or presumed "trapped air" (e.g., bowel obstruction, pneumothorax, perforated viscus, or middle ear infection).

#### **Opioid Analgesics (Fentanyl)**

Opioids (narcotic agents) are widely used and well-established analgesics. Although morphine is the prototype drug in this class, and meperidine also has been used extensively in the past, fentanyl has rapidly become the opioid agent of choice for children requiring potent analgesia during procedural sedation. Fentanyl is a synthetic opioid that has 75 to 125 times the potency of morphine and a *very rapid IV onset of action* (2 to 3 minutes) with a relatively short duration of action (30 to 60 minutes). It is administered in an initial IV dose of 0.5 to 1  $\mu$ g/kg and its pharmacokinetics permit smooth and safe titration either alone or in combination with midazolam at intervals of approximately 3 minutes until the desired effect is achieved.

Fentanyl has additional *advantages* over the longer-acting narcotic agents. It lacks the histamine release characteristic of morphine and the buildup of very-long-acting metabolites occasionally seen with meperidine (the so-called serotonin surge syndrome). It is also effective when administered *intranasally* or *by nebulizer*.

Adverse effects of fentanyl include hypoxemia and respiratory depression. Chest wall and glottic rigidity are uncommon but serious complications and have been reported in neonates receiving a single dose of fentanyl of between 3 and 5  $\mu g/kg$ . In fact, fentanyl has the highest reported complication rate of any agent used for procedural analgesia and sedation. However, fentanyl is rarely used as a single agent so it is likely that much of the excess risk is due to polypharmacy. The practicing physician needs always to remain vigilant when using opioid–sedative combinations, especially when three or more medications have been administered.

The antagonist naloxone is an effective reversal agent for fentanyl. It is administered IV at a dose of 0.1 mg/kg for children 0 to 5 years of age and 2 mg/kg for children older than 5 years of age. The dose can be repeated. Its onset of action is 1 to 2 minutes, with a duration of effect of 20 to 40 minutes, resulting in complete reversal as a single dose most of the time when used with fentanyl. Incidentally, when used to reverse the effects of meperidine, naloxone can result in normeperidine-induced seizures. If glottic or chest wall rigidity occurs, a neuromuscular blocking agent such as succinylcholine, rocuronium, or vecuronium may need to be administered to achieve an oral or endotracheal airway, along with bag-mask positive-pressure ventilation.

If any significant sedation and anesthesia is going to be used other than basic anxiolytics (what was formerly called "conscious sedation"), strict adherence to safety and established guidelines is imperative (also see Chapter 2, Procedural Sedation and Analgesia).

# **EQUIPMENT**

The equipment required for pediatric sedation and analgesia comprises everything that is needed to effectively and safely monitor the patient through induction, maintenance, and recovery from the effects of the medications used. In addition, equipment needs to be readily at hand to manage any complication that may arise from the unintended escalation of sedation level to either deep sedation or general anesthesia. A list of basic essential equipment appears in Box 7-1.

# **PRESEDATION EVALUATION**

Box 7-2 summarizes a comprehensive and accepted set of required components for the safe administration of procedural sedation in the pediatric patient. This sedation model was developed at the Children's Hospital of Wisconsin. Pediatric sedation does not relieve the physician of the need to explain the anticipated procedure to both the child (when their cognitive level warrants) and the parent or guardian. Informed consent for both the sedation and the procedure should be obtained and documented in the medical record. An example of a procedural sedation informed consent form is available online at www.expertconsult.com.

# Box 7-1. Equipment Needs and Considerations for Pediatric Procedural Sedation

- Oxygen with a system that is capable of administering at least 90% O<sub>2</sub> at 10 L/min for 60 minutes
- Bag-mask system for positive-pressure ventilation
- Laryngoscope with appropriately sized blades and endotracheal tubes
- Suction catheters and apparatus
- Emergency cart with appropriate medications and Breslow tape
- Defibrillator
- Pulse oximeter
- Electrocardiograph monitor
- Noninvasive blood pressure apparatus
- Emergency antagonists, including naloxone and flumazenil
- IV start kit and appropriately sized IV catheters
- 500-mL bags of normal saline and Ringer's lactate
- Telephone or radio for summoning assistance in an emergency
- End-tidal CO<sub>2</sub> monitor (when available)
- Equipment for administering blood and blood components need to be readily available if transfusion becomes necessary
- Intraosseous catheter kit should be immediately available if IV access is lost and a standard IV line cannot be started

The majority of this equipment is available in the Banyan Kit (a "crash cart in a suitcase"), available commercially.

A focused history and physical assessment should be performed before administering any sedative or analgesic agent. This evaluation can be performed any time within 30 days of an intended procedure, depending on institutional requirements and standards. However, the patient must be reassessed immediately before

Essential components of the Children's Hospital of Wisconsin structured sedation program, adapted from American Society of Anesthesiologists (ASA) and American Academy of Pediatrics (AAP) guidelines. Each of these components is specifically prompted on a uniform sedation documentation record.

TABLE 7-2 Airway Assessment				
Physical Characteristic	Specific Concerns			
Body habitus	Obese vs. thin			
Presence of micrognathia (see Fig. 7-1) Dentition status	Size and length of neck Receding mandible Size of mandible in relation to face Protruding incisors (buck teeth) Poor dental condition; caries Loose teeth or crowns			
Joint mobility	Distance between upper and lower teeth, associated with the presence of high-arched palate  Mobility of the head at the atlanto-occipital joint (see Fig. 7-2)  Mobility of the mandible at the temporomandibular joint  Mallampati classification (see Chapter 2, Procedural Sedation and Analgesia, Fig. 2-2)			
Thyromental distance (>6 cm, three fingerbreadths)	By measuring the thyromental distance, the anatomic proximity of the glottis to the mandible and base of the tongue can be gauged			
Intraoral concerns	Status of tonsils, intraoral tissues, torus palatinus, tumors, trauma Redundant tissue Presence of neonatal teeth Intra-oral, lingual, or labial body ornaments			
Nasal concerns	Body ornaments: studs and rings Patient may require a nasal airway rather than oral			

initiating procedural sedation to ensure his or her suitability for sedation as well as to reconfirm the appropriateness of the planned sedation regimen. The sedation plan and choice of sedative/analgesic agent(s) should be clearly documented on the presedation evaluation form.

The history should include allergies, use of medications or illicit drugs, diseases, operations, hospitalizations, previous exposure to sedation or general anesthesia, untoward reactions to anesthetic agents in the past, relevant family history, and the time and content of the last oral intake. The physical examination should include auscultation of the heart and lungs as well as a careful assessment of the airway (Table 7-2 and Figs. 7-1 and 7-2). Special attention should be given to identifying anatomic or clinical conditions that

Figure 7-1 Micrognathia.

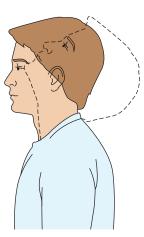

Figure 7-2 Mobility of the head at the atlanto-occipital joint.

might interfere with endotracheal intubation and resuscitation should they become necessary. These conditions are summarized in Box 7-3.

Pediatric patients need to be assigned an ASA Physical Status Classification before performing any emergency or elective procedure. This classification is summarized in Chapter 2, Procedural Sedation and Analgesia, Table 2-2.

A pediatric patient's suitability for mild, moderate, or deep sedation outside of the operating room can range from excellent to very poor in each of the ASA classes, but is generally expected to be good for classes I and II. Formal published recommendations suggest that an anesthesiologist or subspecialist should be consulted for patients with ASA classes of III and IV to assist with airway abnormalities and management as well as other special needs. At the least, in clinical settings where such assistance is unavailable, a second trained and experienced physician should be consulted whose entire focus is the management of sedation throughout the procedure. For elective procedures, transfer to a larger facility where such help is available should be seriously considered.

#### **Fasting before Sedation**

There is limited evidence to support an optimum duration of fasting before sedation to reduce the risk of aspiration. The ASA guidelines, which are based on expert opinion and consensus, recommend a minimum fasting period of 2 hours for clear fluids, 4 hours for breast

# Box 7-3. Sedation Graded Risk Assessment Tool—Sedation Risk Factors\*

Snoring, stridor, or sleep apnea Craniofacial malformation History of airway difficulty Vomiting, bowel obstruction Gastroesophageal reflux Pneumonia or oxygen requirement Reactive airways disease Hypovolemia, cardiac disease Sepsis Altered mental status History of sedation failure Inadequate NPO time No identified risk factors

<sup>\*</sup>Medical conditions and patient characteristics with known potential for increasing the risk of procedural sedation are specifically prompted on the sedation record.

**TABLE 7-3** Fasting Guidelines before Procedural Sedation

Age	Milk/Solid	Clear Liquid/Breast Milk
Children <6 mo	4 hr	2 hr
Children >6 mo	6 hr	2 hr
Other children and adults	6 hr	6 hr

If food or fluids are ingested within these time periods

- · The procedure may be delayed
- The case may be referred to a licensed anesthesia provider to help protect the airway.
- In emergent and urgent situations, the increased risk of aspiration must be weighed against the benefits of the procedure. The lightest effective sedation should be used.

milk, and 6 hours for formula, nonhuman milk, and solids. For children with normal airways and no clinical predisposition to aspiration, a systematic review of randomized trials failed to find any benefit for fasting from fluids for more than 6 hours compared with 2 hours. In addition, no statistically significant differences in intraoperative gastric volumes and pH were noted. According to an expert panel who published their findings in *Annals of Emergency Medicine* in 2007, the following considerations related to the risk of aspiration should dictate the planned depth and length of procedural sedation in the emergency department:

- Possibility of a difficult airway
- Conditions predisposing to esophageal reflux, including elevated intracranial pressure, gastritis, bowel obstruction, or ileus
- Age less than 6 months
- Severe systemic disease with functional limitation (ASA) class
   3)
- Timing and nature of last oral intake
- Urgency of procedure

See Table 7-3 for a useful summary of accepted fasting guidelines before sedation.

# **PERSONNEL**

Physicians who administer procedural sedation must fully understand the pharmacology of the medications they use. They must also have the breadth of clinical experience and judgment to select a regimen that is appropriate for both the patient and the intended procedure. Because altered consciousness represents a continuum and not discrete "quantum" levels, clinicians should have the requisite training and current skill to deal effectively with complications arising from the patient drifting to the next deeper level of sedation than that intended.

Two trained and credentialed individuals are required when a patient is significantly sedated for a procedure, one to perform the procedure and the second to administer and monitor the sedation. Ideally, both individuals would be physicians, and this choice is probably prudent if deep sedation is planned (at the least, the second individual should be a licensed nurse anesthetist). In practice, the second individual is either a nurse or trained assistant (certified medical assistant, certified nursing assistant, or respiratory therapist). He or she monitors the patient and documents vital signs, level of consciousness, timing and dose of medication administration, and any complications. If the assistant is not a physician trained in sedation management, it is imperative that the physician in charge of the procedure be able to stop the procedure at any time to manage complications arising from sedation and analgesia.

### **MONITORING**

Documentation of any procedure should be scrupulous and complete and include a description of the level of responsiveness of the

patient, otherwise known as the sedation score (see Chapter 2, Procedural Sedation and Analgesia, Table 2-1). Document the issues discussed in obtaining informed consent in the patient record. Some medicolegal experts also recommend asking a parent or guardian to sign a form listing each procedure that the physician might perform. With regard to pediatric sedation, the physician should document how well the patient tolerated the method used. If side effects are noted or complications encountered, full documentation—including a careful record of all measures and medications used in dealing with them—must be given in the sedation report in the patient's medical record. A time-based record of heart rate (electrocardiographic monitor or pulse oximeter), oxygen saturation (pulse oximeter), end-tidal CO<sub>2</sub> (if used), as well as nursing assessments and monitoring must be made until the patient is fully recovered. For patients with an underlying illness or for whom deep sedation is planned, these measurements along with vital signs should be taken and recorded at least every 5 minutes.

The nurse should record all medications given (dose, route of administration, and time given), as well as fluids, blood loss, and any unusual events or complications. Supplemental oxygen should be administered prophylactically in all cases. IV access is strongly encouraged during pediatric sedation and analgesia, although it is not absolutely necessary for lighter levels of sedation or when sedative agents are administered by oral, nasal, rectal, or intramuscular routes. However, in these cases, equipment and skilled personnel capable of immediately establishing vascular access need to be present.

#### **RECOVERY AND DISCHARGE CRITERIA**

Monitoring must be continued by trained personnel until the infant or child has met pre-established criteria for safe discharge. These criteria include the following:

- Airway patency and stable cardiovascular function
- Easy arousability with intact protective reflexes
- Ability to talk (if age appropriate)
- Ability to sit up without assistance (if age appropriate)
- Adequate level of hydration

Disabled patients as well as young children and infants should be observed until they return to the same level of responsiveness noted before sedation. Numerous scoring systems have been published. Table 7-4 outlines the Aldrete Recovery Scale, a common system used at many health care institutions throughout the United States. As most of my residents and nurses have heard me chant, "When they meet the Aldrete, the patient's all ready."

TABLE 7-4	Aldrete Recovery Score
Activity	Voluntary movement of all limbs to command— 2 points
	Voluntary movement of two extremities to command—I point
	Unable to move—0 points
	Apneic—0 points
Respiration	Breathe deeply and cough—2 points
	Dyspnea, hypoventilation—I point
Circulation	BP ±20 mm Hg of preanesthesia level—2 points
	BP ±20–50 mm Hg of preanesthesia level—1 point
	BP >50 mm Hg of preanesthesia level—0 point
Consciousness	Fully awake—2 points
	Arousable—I point
	Unresponsive—0 points
Color	Pink—2 points
	Pale, blotchy—I point
	Cyanotic—0 points

BP, blood pressure.

\*Total score must be greater than 8 at the conclusion of the monitoring.

# **POSTSEDATION CONCERNS**

Available evidence suggests that infants and children who have not experienced an adverse event during sedation can be safely discharged after 30 minutes of observation and monitoring.

What about the risk of adverse events occurring after discharge? In a large, well-designed, prospective study of 1341 pediatric sedation events occurring in the emergency department setting, adverse reactions were noted in 14% of patients and potentially life-threatening events occurred in 12%. Only 8% of all adverse events occurred after the procedure. Every child who experienced a post-procedure event had a similar adverse effect earlier in the sedation. All serious, potentially life-threatening events occurred within 25 minutes of the last sedative/analgesic dose. Parents or guardians should nevertheless be advised that minor side effects may occur after discharge from the recovery area and that full recovery after moderate or deep sedation may be prolonged. Discharge instructions should include the telephone number of a trained staff member to field any parental questions or concerns.

## **PATIENT EDUCATION GUIDES**

See the sample patient and parent education handout available online at www.expertconsult.com.

# **CPT/BILLING CODES**

- 99143 Moderate sedation services provided by the same physician performing the diagnostic or therapeutic service that the sedation supports, requiring the presence of an independent trained observer to assist in the monitoring of the patient's level of consciousness and physiologic status in patients younger than 5 years of age, first 30 minutes intra-service time
- 99144 Patients age 5 years or older, first 30 minutes intra-service time
- 99145 Each additional 15 minutes intra-service time. (List separately in addition to code for primary service)

NOTE: This code list does not include simple or minimal office sedation techniques (anxiolysis).

# PERIPHERAL NERVE BLOCKS AND FIELD BLOCKS

Morteza Khodaee • Barbara F. Kelly

Many ambulatory procedures lend themselves well to local anesthesia with a field block or a peripheral nerve block. A *field block* is a method of providing anesthesia to a relatively small area by injecting a "wall" of anesthetic solution across the path of the nerves supplying the operative field (Fig. 8-1). Instead of the injection being made directly into the area of the procedure, it is made into the soft tissue some distance away, where the nerves are situated. Advantages include longer duration of anesthesia and no distortion of the operative field.

A *nerve block* is the infiltration of a local anesthetic near the nerve branch supplying sensation to a particular area. Blocking a nerve provides longer duration of anesthesia than that obtained with local cutaneous infiltration. Knowledge of the anatomy of peripheral nerves and a scrupulous sterile technique are important for successful peripheral nerve blocks. Use of this technique may reduce the amount of anesthetic needed, reduce distortion of tissues, and allow palpation of pathology to be excised.

Ultrasonography-guided nerve blocks may increase block quality parameters and decrease the potential complications (see Chapter 185, Musculoskeletal Ultrasonography).

In some sites (e.g., the breast) a nerve block cannot be obtained, and thus the field block is the only reasonable alternative. However, where possible, the nerve block may be the procedure of choice.

Also see Chapter 9, Oral and Facial Anesthesia.

### **INDICATIONS**

- When local anesthetic at the site of incision may be ineffective (e.g., with infected tissue the pH is lower)
- When the edema from the local anesthetic injection would distort anatomic landmarks and make approximation and repair difficult
- To preserve palpation of the deep tissue to be excised
- When repairs or excisions are quite large and prohibit the use of large amounts of anesthetic
- For fracture and dislocation care
- For nail removal

# **CONTRAINDICATIONS**

# **Absolute Contraindications**

- If it would require injecting through infected tissue
- Presence of septicemia
- Profound bleeding tendencies
- History of allergy to local anesthetics (see Chapter 4, Local Anesthesia, and Chapter 5, Local and Topical Anesthetic Complications)

#### **Relative Contraindications**

- Any neurologic damage existing before the procedure. Document findings before injection.
- In general, epinephrine-containing solutions should not be used in the fingers, toes, penis, nose, or ear, nor should epinephrine be used in areas with poor vascular supply. Use caution in patients with diabetes, peripheral vascular disease, or other conditions affecting vascular supply.

#### **EQUIPMENT**

- Sterile field and agent for sterile preparation of skin
- Local anesthetic agent (see Chapter 4, Local Anesthesia), usually 2% lidocaine without epinephrine
- 18-gauge needle to draw up solution
- 25- to 30-gauge needle for injection (1 to 10 mL)
- Appropriate-size syringe
- Gloves

# PREPROCEDURE PATIENT PREPARATION

There are few complications with field and nerve blocks. The benefits of the blocks versus the alternatives (e.g., general anesthesia, no anesthesia, and Bier block) may be explained. Depending on the agent used, the duration of anesthesia may be prolonged, and the patient should be informed of the expected length of action. In rare instances a nerve could be traumatized, but long-term consequences are rare. Any precautionary advice, such as avoidance of heat or cold after the procedure, should be given to the patient. The possibility of paresthesia during the injection should be explained.

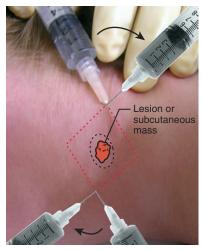

# **TECHNIQUE**

# Field Block

The technique of administering a field block is similar to the technique discussed for local anesthetics (see Chapter 4, Local Anesthesia). In this instance, however, the area to be incised is spared from the injection. Rather, the area around the site is injected (see Fig. 8-1). Repeat injections are made until the entire border of the field has been infiltrated. Allowing 5 to 10 minutes for the block to take effect improves the resulting anesthesia.

### **Nerve Block**

1. Before beginning any peripheral nerve block, perform a neurologic examination of the area to be anesthetized and document

**Figure 8-1** Field block technique. This method of injecting around the lesion prevents distortion of the anatomy and allows any deeper central lesion to remain palpable. The *red lines* indicate the path of the needle (four separate insertions). The *black line* indicates the incision line.

- the results in the medical record. If any neurologic defect is present, include a description of it in the document of informed consent for the procedure, and have the patient sign a statement agreeing that the defect was present before the administration of the anesthetic.
- 2. Identify the appropriate nerve(s) and anatomic sites to accomplish the block.
- 3. Carefully clean and prepare the skin over the injection site in a sterile fashion.

- 4. Draw up the anesthetic. Usually a 25- to 30-gauge needle can be used to inject the anesthetic. The amount of anesthetic used varies depending on the location of the nerve.
- 5. Insert the needle into the site, withdrawing the plunger slightly to test for intravascular placement of the needle and moving the needle if necessary to avoid intravascular injection. If the patient experiences paresthesia, withdraw the needle slightly because it is probably within the nerve. The goal is to inject perineurally, not into the nerve itself. If no paresthesia is noted at the expected site, confirm that there is no potential for intravascular injection and slowly inject the anesthetic. If the proper site has been identified, often as little as 1 or 2 mL will provide an excellent anesthetic field.
- 6. Allow 5 to 15 minutes for the block to take effect. Confirm anesthesia to pinprick before making an incision.

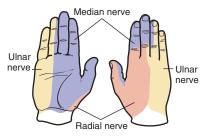

#### **Common Nerve Blocks**

Also see Chapter 9, Oral and Facial Anesthesia.

1. Digital block of finger or toe and nail anesthesia (Fig. 8-2): Use 4 to 6 mL of 1% to 2% lidocaine without epinephrine for each finger, and 6 to 8 mL of the same for toes. Insert the 25- to 30-gauge, ½-inch needle fully into the skin at the base of the finger or toe into the web space and inject 1 mL (see Fig. 8-2B). Repeat this on the other side unless it is the first or fifth digit. Then insert the needle perpendicular to the bone at the base of the digit, touch the bone, and pull back a little (see Fig. 8-2B and D). Inject 1 mL into the lateral aspect, then 1 mL across the dorsal and another 1 mL under the ventral surfaces in the subcutaneous space. Repeat this on the contralateral side of the digit. Alternatively, the needle can be inserted dorsally, then ventrally (see Fig. 8-2E). The dorsal digital nerves in both

Figure 8-2 Anatomy and injection technique for digital nerve block. **A,** The four digital nerves. The bone is used as a landmark to find the proper plane of the dorsal digital nerve. **B,** Site of injection in web space. When removing a toenail, an additional I mL of anesthetic can be placed just proximal to the nail. **C** and **D,** Digital nerve block of the finger. The sites of the nerves are injected bilaterally. Insert the needle and, after touching bone, withdraw slightly and then inject 0.5 mL of anesthetic. **E,** Digital nerve block of the toe, showing an alternative method of injection from the dorsal aspect. This is followed by a ventral injection in the same manner. **F,** Nail wing block.

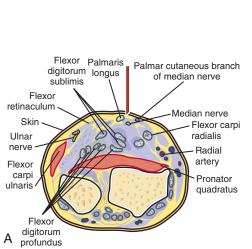

**Figure 8-3** Distribution of cutaneous sensation of the hand by the radial, ulnar, and median nerves.

instances lie close to bone. As the bone is touched with the needle tip, withdraw 1 or 2 mm and inject the solution.

Nail anesthesia can be achieved by a *wing block* as well (see Fig. 8-2F). The injection site is 5 to 8 mm proximal and lateral to the corner of the nail. Direct the needle distally at a 45-degree angle, advance until bone is reached, and pull back slightly to avoid injecting the periosteum. Slowly inject 0.3 to 0.5 mL of anesthetic. This will blanch both the proximal and the lateral nail folds in a "winglike" pattern. To obtain full lateral anesthesia, a second injection of 0.3 to 0.5 mL into the entire length of the lateral nail fold should be performed in addition to the wing block to obtain anesthesia for the lateral half of the nail. A similar procedure can then be carried out on the other side of the toe if full nail anesthesia is needed.

2. Median nerve block: The median nerve supplies sensation to the palmar aspect of the thumb and index and middle fingers. In addition, the radial half of the palm is supplied by the median nerve (Fig. 8-3). A nerve block may be indicated for extensive lacerations and incisions in these areas. The median nerve lies between the flexor carpi radialis and the palmaris longus (Fig. 8-4A). With slight flexion of the wrist and simultaneous flexion of the middle finger only at the metacarpophalangeal joint, the palmaris longus stands out (Fig. 8-4B). The injection should be made at the flexor crease of the wrist just radial to the palmaris longus. Use 3 to 5 mL of 1% lidocaine without epinephrine (Fig. 8-4B and C).

- 3. Ulnar nerve block: The ulnar nerve innervates the dorsal and palmar aspects on the ulnar side of the hand (fifth finger and ulnar side of the fourth finger; see Fig. 8-3). The ulnar nerve divides to dorsal and palmar branches 4 to 5 cm proximal to the wrist. Therefore, the easiest way to obtain an ulnar block is to inject the ulnar nerve at the elbow where the nerve lies only 0.5 cm below the skin, between the medial epicondyle and the olecranon (Fig. 8-5A). Each branch can also be blocked separately at the wrist (Fig. 8-5B). The risk of nerve compression and postprocedure paresthesia is higher at the elbow. For all nerve blocks, it is best not to inject directly into the nerve but around it; 2 to 3 mL of 1% lidocaine should be sufficient here.
- **4.** Radial nerve block: The radial nerve innervates the dorsum of the thumb, the index and middle fingers, and the radial portion of the dorsum of the hand (see Fig. 8-3). Because of multiple divisions of the radial nerve, 10 mL of anesthetic is often required to obtain good results. Inject 3 mL of solution along the lateral border of the radial artery two fingerbreadths above the wrist. Then lay a superficial ring of solution from this point extending dorsally over the border of the wrist and into the anatomic snuffbox area created by the tendons of the abductor pollicis longus and extensor pollicis brevis muscles. The nerve is in the superficial fascia just deep to the skin (Fig. 8-6).
- 5. Facial nerve blocks (also see Chapter 9, Oral and Facial Anesthesia):
  - Supraorbital and supratrochlear nerve blocks (forehead block): The supraorbital and supratrochlear nerves innervate the forehead and anterior scalp. The nerves exit at the supraorbital ridge. To ensure that both nerves have been injected, infiltrate just above the bone beneath the entire medial two thirds of the eyebrow (Fig. 8-7A).
  - Infraorbital nerve block: Palpate a notch in the infraorbital rim. The infraorbital nerve exits just beneath this small notch. Infiltrate through the skin directly over the infraorbital area, or use an intraoral technique. The latter approach requires a 1½-inch needle, ideally 27 gauge. Introduce the needle at the gingival–buccal margin over the maxillary canine tooth. Advance it under the skin until the infraorbital foramen is reached. Use approximately 2 mL of anesthetic. This block is used especially to repair upper lip lacerations so that the

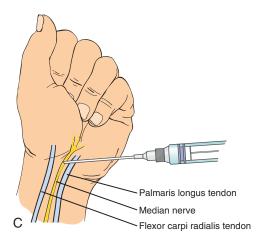

Figure 8-4 Median nerve block. A, Cross-sectional anatomy of the wrist (left wrist, palm up). B, Site of injection between flexor carpi radialis tendon (arrow) and palmaris longus tendon (arrowhead). C, Location of injection. (A and C, Adapted from Trott A: Wounds and Lacerations: Emergency Care and Closure, 3rd ed. St. Louis, Mosby, 1997.)

**Figure 8-5 A,** Site of an ulnar nerve block. **B,** Site of injection at wrist for palmar branch deep between the flexor carpi ulnaris tendon and ulnar artery (*arrow*), and for dorsal branch subcutaneously distal to the ulnar styloid process (needle).

vermilion border can be approximated appropriately. It can also be used for lacerations of the lower lateral nose and the lower eyelid (Fig. 8-7B and C).

- Mental nerve block: The mental nerve innervates the lower half of the lip. To avoid distortion that is inevitable with local injection around the vermilion border, inject the mental nerve. In adults the nerve exits the mandible just inferior to the second mandibular bicuspid, midway between the upper and lower edges of the mandible, and 2.5 cm from the midline of the jaw. As with the infraorbital nerve injection, introduce the needle at the gingival–buccal margin inferior to the second bicuspid. Another option is a transcutaneous approach 1.5 cm posterior and lateral to the mental foramen, which can be palpated through the skin. After aspiration, inject 2 mL of anesthetic (Fig. 8-7D and E).
- **Lip block:** The *upper lip* can also be blocked by injection of 5 to 10 mL of anesthetic along two lines in the direction of the nasal alae (Fig. 8-7F). An option for blocking the *lower lip* is to insert the needle at the midpoint of the chin, aiming toward the angle of the mouth (Fig. 8-7G).
- **6. Ear block:** Because of complex innervations of the ear, it is impossible to infiltrate a solitary nerve. In addition, it is difficult to infiltrate *over* the cartilage because the skin here is so thin. A complete block of the auricle can be obtained by infiltrating completely around the ear with approximately 10 mL of 1% lidocaine *without* epinephrine (Fig. 8-8). This block will not numb the concha or the ear canal.

- 7. Foot block: Foot blocks are indicated not so much to prevent distortion but rather to limit discomfort. The sole of the foot is exquisitely sensitive to injection, and it is often subject to puncture wounds, lacerations, and foreign bodies. Nerve blocks can actually be more comfortable than direct infiltration and are discussed in detail in the following.
  - Posterior ankle block: The sural nerve (Su) runs behind the fibula and lateral malleolus to supply the lateral aspect of the heel and foot. The tibial nerve (LP, MP, MC) is found between the Achilles tendon and the medial malleolus, and its course is along the posterior tibial artery. The tibial nerve supplies the medial portion of the sole and the medial side of the foot (Fig. 8-9). To block the sural nerve, insert the needle lateral to the Achilles tendon 1 to 2 cm proximal to the level of the distal tip of the lateral malleolus. To ensure that the entire nerve is infiltrated, introduce the needle several times in a fan-shaped motion, directing it to the posterior medial aspect of the fibula (Fig. 8-10).

To obtain a tibial nerve block, identify the posterior tibial pulsation. Pass the needle medial to the Achilles tendon toward the posterior tibial artery behind the medial malleolus. Infiltration is around the artery, and careful aspiration must be carried out to prevent intra-arterial injection (Fig. 8-11).

Anterior ankle block: The superficial peroneal nerve (SP) supplies the majority of the dorsal foot. It can be blocked by inserting the needle subcutaneously at the superior and medial aspect of the medial malleolus (Fig. 8-12).

# Oral and Facial Anesthesia

Larry Skoczylas

The ability to perform site-specific oral and facial regional nerve blocks is an important adjunct to almost any medical practice. Physicians are often the first practitioners to evaluate facial pain. This pain may be due to trauma, localized swelling and infection, or even facial neuralgias and tics. Properly infiltrated local anesthetic can eliminate discomfort when closing wounds, can provide pain control to a patient with a tooth abscess until he or she can be treated, or can be used as a diagnostic test to see if a suspected neuralgia is due to a peripheral or a central source. If peripheral, pain should be eliminated by the anesthesia. If central, the pain may persist.

This discussion involves both intraoral and extraoral anesthetic techniques. Therefore, an understanding of regional anatomy is crucial to properly perform these infiltrations and nerve blocks. The sensory innervation of the face and oral cavity is primarily from the trigeminal nerve (fifth cranial nerve). This nerve is divided into ophthalmic  $(V_1)$ , maxillary  $(V_2)$ , and mandibular branches  $(V_3; Figs. 9-1 \text{ and } 9-2)$ .

The ophthalmic division is purely sensory and supplies the eyeball, conjunctiva, lacrimal gland, parts of the mucous membrane of the nose, paranasal sinuses, and the skin of the forehead, eyes, and nose. When this nerve is paralyzed, the ocular conjunctiva becomes insensitive to touch. Sensory anesthesia of  $V_1$  is usually obtained by local infiltration with a supraperiosteal extraoral block.

The maxillary division, like the ophthalmic division, is purely sensory. It supplies innervation to the skin of the middle portion of the face, lower eyelid, side of the nose, upper lip, maxillary teeth, and periodontal tissues. In addition, this nerve is sensory to the mucous membrane of the nasopharynx, maxillary sinus, tonsils, and hard and soft palate. This nerve can be blocked by both intraoral and extraoral injection.

The mandibular division has a large sensory as well as a small motor component. Blockage of the motor division can lead to decreased muscle function of the masseter, temporalis, pterygoid, mylohyoid, digastric, and soft palate elevators. Sensory innervation is to the temporal region and ear, cheek, lower lip and chin, parotid gland, temporomandibular joint, and mastoid area. Orally, the mandibular teeth and periosteal tissues, bone of the mandible, anterior two thirds of the tongue, and all intraoral mucosa are affected. The majority of anesthetic given for the mandibular division is intraoral, although some extraoral blocks may be indicated.

# **INDICATIONS**

- Whenever anesthesia is desired in a fairly large anatomic area
- To limit the amount of medication given
- For laceration repair or lesion removal
- Around infection sites for incision and drainage
- To limit distortion of tissues and allow a better repair
- To anesthetize periosteum before more painful subperiosteal procedures such as tooth removal
- As a diagnostic block to determine the cause or site of pain
- To control pain

#### **CONTRAINDICATIONS**

- History of allergy or reaction to local anesthetics (or bisulfite/ parabens preservatives)
- Risk of hematoma (e.g., in patients with hemophilia or anticoagulant use); trauma to vascular bundles can increase risk of bleeding and hematoma (relative contraindication)
- Uncooperative patients (e.g., pediatric patients or patients with mental retardation may require sedation before local anesthetic; relative contraindication)

#### **COMPLICATIONS**

See Chapter 5, Local and Topical Anesthetic Complications.

- Syncope: Most common untoward reaction to anesthetic injections, often resulting from pain during the injection. A semisupine or supine position and slow injection technique are recommended.
- Broken needle: Very rare, but it is best to always leave some needle showing and not to "bury" to the hub when injecting.
- *Hematoma:* Rare, often resulting from torn capillaries or vessels that are punctured during injection.
- Persistent paresthesia: Occurs after the anesthetic should have worn off. Indicates damage to the nerve from physical or local chemical trauma. Can be temporary or permanent.
- *Ischemic ulcer:* Usually resulting from vasoconstrictor use in relatively *awascular* tissue (e.g., subperiosteally in the hard palate). Skin is very vascular, and ischemia is extremely rare when local anesthetic with epinephrine of a low concentration (1/100,000 or 1/200,000) is used.
- Blanching: Occurs at the site of injection because of pressure of anesthetic and vasoconstriction. If remote from the injection site, then it is probably due to inadvertent intravascular injection. No treatment is needed.
- Tachycardia: Can occur from pain of injection, but it is most likely due to intravascular injection or rapid absorption of local anesthetic with epinephrine.
- Paralysis: Results from inadvertent anesthesia of facial nerve (seventh cranial nerve). It is usually temporary. If longer-acting anesthetics such as bupivacaine are used and the patient cannot close the eyelid, the lid can be taped down (to avoid dryness of the eye) until the anesthetic wears off.
- Visual disturbance: Rare, probably due to vascular spasm or intraarterial injection. Normal vision usually returns in about 30 minutes.
- Overdosage: Seizures and cardiac arrhythmias.

# **EQUIPMENT**

- 10-mL syringe with Luer-Lok hub (for aspiration)
- 1- or 1½-inch (25- to 30-gauge) needle
- Local anesthetic, such as 2<sup>n</sup> lidocaine with or without 1:100,000 epinephrine, or 0.5% bupivacaine with or without 1:200,000 epinephrine

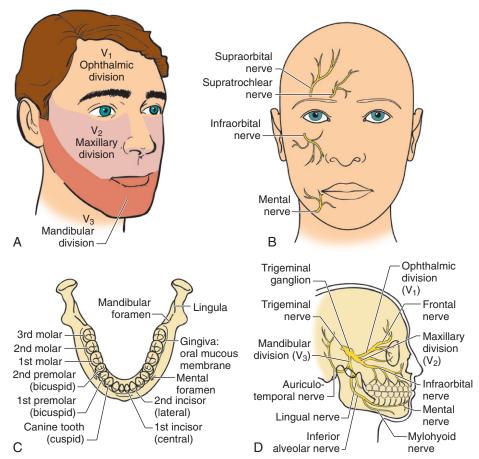

Figure 9-1 Sensory innervation of the face and oral cavity is primarily from the trigeminal nerve. **A,** The trigeminal nerve is divided into three branches: the ophthalmic branch  $(V_1)$ , the maxillary branch  $(V_2)$ , and the mandibular branch  $(V_3)$ . **B,** Sensory distribution of the terminal branches of the trigeminal nerve: the supratrochlear nerve, supraorbital nerve, infraorbital nerve, and mental nerve. **C,** Anatomy of the mandibular arch and the lower teeth. **D,** Distribution of the trigeminal nerve. (**D,** Modified from Roberts JR, Hedges JR: Clinical Procedures in Emergency Medicine, 2nd ed. Philadelphia, WB Saunders, 1991.)

- Mepivacaine (pK<sub>a</sub> 7.6; may give better anesthesia in infected tissue, which usually has an acidic environment [pK<sub>a</sub> <7.5])</li>
- Dental aspirating syringe (a good alternative; would need specific anesthetic carpules and needles for this system)

# **GENERAL TECHNIQUE**

1. Anesthetic solution is usually deposited just above the bone around the nerve trunks in the submucosa or subcutaneous tissue, where the nerves exit from the bone itself (e.g., supraorbital,

- infraorbital, or mental nerves). This technique is known as a *supraperiosteal injection*. It may be approached from either an intraoral or extraoral route, depending on the nerve block desired.
- 2. If going through facial skin, clean the skin with alcohol. If giving local anesthetic to repair traumatic lacerations, clean thoroughly with normal saline. Tent or support the tissue and slowly infiltrate (for 30–60 seconds) into the area to be addressed. Identify landmarks before infiltration; they can become "ballooned" and hard to appreciate after local anesthetic is given.

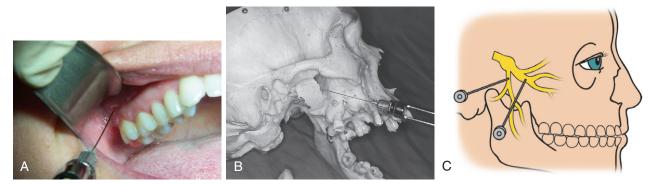

Figure 9-2 Maxillary nerve block. **A,** View with patient. **B,** Angle of needle to obtain intraoral maxillary (V<sub>2</sub>) block. **C,** Location of needles for extraoral block (not described). Note that needle is not placed directly into the nerve.

3. If going through the oral mucosa, tissues are rarely scrubbed before injection. Cleaning any obvious debris in a trauma site with normal saline is indicated before closure. Lift up and tent lips or cheek. The target of the injection should be the procedure site.

#### **INTRAORAL APPROACHES**

# Maxillary (V2) Intraoral Nerve Block

See Figures 9-1 and 9-2.

#### Indications

- Anesthesia of the entire hemimaxilla for trauma repair or pathologic surgery
- For diagnostic blocks of the second division of the trigeminal nerve to evaluate neuralgias and tics
- To aid in anesthetizing infected sites or areas of tooth removal

#### Advantage

Decreases the amount of anesthetic solution used and the number of injection sites needed for maxillary anesthesia.

#### Technique

- 1. Place patient in a semisupine position. Partially open the patient's mouth and pull mandible toward side of injection (mandible to right for upper right injection).
- 2. Pull taut and retract cheek with index finger to gain visibility.
- 3. Aim for the area posterior and lateral to back of upper jaw (pterygopalatine fossa area). The area of insertion is the height of the mucobuccal fold above the distal aspect of the upper wisdom tooth area (lateral to the approximate junction of the hard and soft palate). Orient the bevel of the needle toward the bone.
- 4. Advance the needle slowly in the superomedial direction to a depth of about 30 mm (if necessary, measure on the needle beforehand to get an idea of the length).
- 5. No resistance should be felt. If resistance is noted, the angle of the needle toward the midline is too great.
- 6. Aspirate and deposit the local anesthetic (2 to 3 mL): continue to aspirate intermittently throughout the course of injection.

# Mandibular ( $V_3$ ) Intraoral Inferior Alveolar Nerve Block

See Figures 9-1 and 9-3.

# Indications

- For anesthesia of entire hemimandible; can be achieved bilaterally if anesthesia of entire mandible or anterior mandible is needed
- For fracture repair, bone biopsy, removal of teeth, or pain control resulting from tooth infection or swelling

#### Disadvantages

- Not 100% successful (80% to 85%).
- Blind technique (by palpating landmarks). Intraoral swelling can make palpation of landmarks difficult.
- Intraoral landmarks are different in children than in adults. The lingula (a small bony bump) of the inner ramus of the mandible (where the nerve enters the jaw) is at a lower level in children.

#### Technique

- 1. Place the patient in a semisupine position and instruct him or her to keep the mouth open.
- 2. The target site is the lingula, a small bony bump about halfway back on the inner ramus of the mandible, where the inferior alveolar nerve enters the jaw.
- 3. Place the thumb of the noninjecting hand over the pterygomandibular raphe (the band of tissue in the posterior cheek between the upper and lower wisdom teeth). Use the thumb to pull the tissue laterally until the deepest depression in the anterior border of the ramus is felt. This creates a tense area for needle penetration.
- 4. Gently grasp the posterior border of the mandible with the middle finger of the noninjecting hand, as high superiorly as the ear allows. The line between the thumb and finger establishes the vertical height of the target area on the inner aspect of the ramus. The lingula should always be on or just below this line (and will always be below this line in children).
- 5. The anteroposterior position of the nerve (the target site) is located midway between the thumb and middle finger. The line of needle insertion is an oblique angle estimated by placing the barrel of the syringe over the bicuspid teeth (or mid-mandibular body region) of the opposite side.
- 6. The needle is inserted to the target site until bone is gently contacted. Depth of penetration is 1 to 2 cm. Always leave part of the needle showing to identify direction. Correct length should be about one half to three fourths of a 1½-inch needle.
- 7. If bone is contacted before half the length of the needle is inserted, the angle of penetration is usually too anterior. If no bone is contacted, the angle is too parallel to the inner aspect of the ramus of the mandible. In these instances it is best to withdraw the needle and start again.
- 8. Aspirate and slowly inject over 60 seconds. Continue to aspirate intermittently while injecting.

# Akinosi Intraoral Closed Mouth Mandibular (V<sub>3</sub>) Block

See Figure 9-4.

#### **Indications**

- For mandibular V<sub>3</sub> anesthesia
- When the patient is unable to open his or her mouth because of pain, swelling, trismus, or infection

**Figure 9-3** Site of intraoral mandibular  $(V_3)$  inferior alveolar block. **A,** Patient; **B,** skull.

- For an uncooperative patient
- When conventional mandibular block has failed

#### **Technique**

- 1. Place the patient in the same position as that for the  $V_3$  block.
- Place the noninjecting finger (the thumb may be too big) at the greatest depression of the anterior ramus, as previously described for the V<sub>3</sub> block.
- 3. Identify the maxillary tuberosity—essentially a rounded area of bone just past the upper wisdom tooth area intraorally, which is the end of the maxillary bone.
- 4. Hold the barrel of the syringe parallel to the plane of the upper teeth, with the bevel of the needle toward the midline of the upper jaw.
- 5. The needle is inserted at the gingival (gum) level, about 0.5 cm superior to the tooth–gum interface.
- 6. Advance the needle between your finger and the maxillary tuberosity about 25 mm into the tissue, directing the needle slightly laterally to stay parallel to the plane of the upper teeth.
- 7. Aspirate and inject 2 to 3 mL of local anesthetic slowly over 60 seconds. Motor nerve paralysis of the masseter and lateral pterygoid muscles often occurs and can help decrease trismus. There can also be a facial nerve palsy if injection is through the sigmoid notch of the mandibular ramus and into the parotid gland. Maintaining the correct depth of penetration will help decrease this complication.

# **EXTRAORAL APPROACHES**

# **Extraoral Block of Infraorbital Nerve**

See Figures 9-1 and 9-5.

## Indications

- To anesthetize the upper face, lips, or nose for trauma repair or excision
- To provide local anesthetic effect when infection intraorally causes too much pain to tolerate intraoral injection
- For diagnostic nerve block for neuralgias or tics

This is an easy block to administer, whether the intraoral or extraoral approach is used. It is also frequently used because it avoids the distortion created by direct local injection when lip repair and fine approximation are needed to avoid unsightly scars.

#### Disadvantage

The technique is performed by blind palpation of infraorbital foramen.

# Technique

- Palpate the infraorbital foramen just below the lowest level of the infraorbital rim, on a line between the pupil and the corner of the mouth.
- 2. Approach the infraorbital nerve from 1 cm below the bony rim and slightly medial to the palpated foramen. It is *not* necessary to enter the infraorbital foramen.
- 3. Slowly deposit 1 to 3 mL of local anesthetic. Paresthesia of the upper lip is sometimes (but not always) noted when the nerve is touched by the needle before injection.
- 4. For an intraoral approach, use the same anatomic landmarks, and approach the nerve through the mucobuccal fold over the maxillary second bicuspid, aiming at the infraorbital foramen. A long needle will be needed.

# Maxillary Extraoral Block of Supraorbital and Supratrochlear Nerves

See Figures 9-6 and 9-7.

#### Indications

- To anesthetize the forehead (supraorbital nerve lateral, supratrochlear nerve medial)
- Use with infraorbital block to anesthetize periorbital tissues

# Technique

- Palpate the supraorbital foramen, which lies just superior to the supraorbital notch. This lies on a vertical line with the pupil when the eye is focused forward.
- 2. Insert the needle just above the notch and inject 2 to 4 mL of anesthetic. You do *not* need to be injecting directly into the foramen to block the supraorbital nerve.
- 3. The supratrochlear nerve can be blocked by redirecting the needle to 1 cm below and medial to the supraorbital foramen, staying on the bony rim, and injecting another 2 mL.

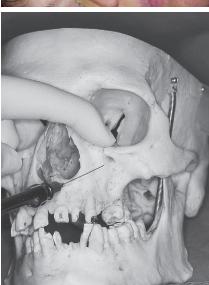

#### Mandibular Extraoral Mental Nerve Block

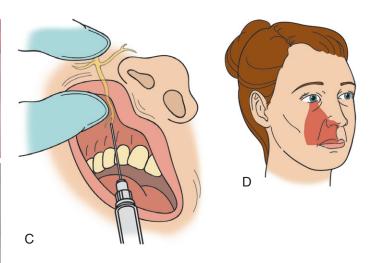

See Figures 9-1 and 9-8.

#### Indications

- To anesthetize the lower lip and chin area for trauma repair or excision
- To provide local anesthetic effect when infection intraorally causes too much pain to tolerate intraoral injection
- For diagnostic nerve blocks for lower face neuralgias and tics

**Figure 9-5** Infraorbital nerve block. **A,** View of patient receiving extraoral infraorbital nerve block. **B,** Proper location for an extraoral infraorbital nerve block. **C,** Intraoral infraorbital nerve block (see text). **D,** Area of anesthesia obtained with infraorbital blocks. (**C** and **D,** From Rosen P, Chan TC, Vilke GM, Sternbach G [eds]: Atlas of Emergency Procedures. St. Louis, Mosby, 2001.)

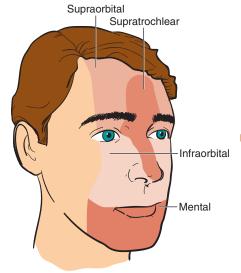

Figure 9-6 Sensory distribution of the terminal branches of the trigeminal nerve.

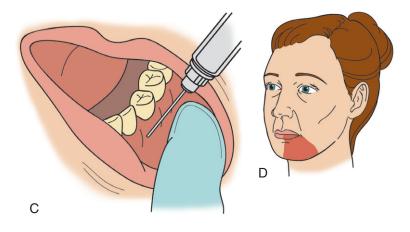

Figure 9-7 A, Supraorbital nerve block. B, Supratrochlear nerve block.

**Figure 9-8** Mental nerve block. **A,** View of patient receiving extraoral mental nerve block. **B,** Site of extraoral mental nerve block. **C,** Intraoral approach. **D,** Area of anesthesia obtained with mental nerve block. (**C** and **D,** From Rosen P, Chan TC, Vilke GM, Sternbach G [eds]: Atlas of Emergency Procedures. St. Louis, Mosby, 2001.)

#### Disadvantage

The technique is performed by blind approximation of the mental nerve position in the mandible.

# Technique

- 1. Approach the mandible extraorally from a position below the bicuspid teeth. The mental nerve foramen is located in the middle of the lower jaw on a line exactly vertically down from the previously described infraorbital nerve foramen. (This area can also be approached vertically from the inferior border of the mandible.)
- 2. Enter the skin with the needle perpendicular to the bone. Advance the needle until bone is touched, then back off 2 to 3 mm. It is *not* necessary to enter the mental foramen.
- 3. Deposit 1 to 3 mL of local anesthetic. Paresthesia of the lower lip is sometimes (but not always) noted when the nerve is touched by the needle.
- 4. The mental nerve can also be approached intraorally. The needle is inserted in front of the teeth at the junction of the gum and

lip mucosa at the level of the premolar/molar teeth (fifth tooth from the midline). Direct the needle inferiorly just above bone for approximately 1 cm and inject 2 to 3 mL of anesthetic.

#### Nose: Skin and Nasal Mucosa

See Figure 9-9.

### Indications

- For paranasal biopsy, or repair of bony or soft tissue nasal trauma (anesthesia for elective rhinoplasty is quite specific and will not be covered)
- Often used in conjunction with extraoral infraorbital nerve block for nasal procedures

# Disadvantage

It can be painful to administer in the awake patient.

#### **Technique**

1. Apply topical spray anesthetic to each nostril.

**Figure 9-9 A,** View of patient receiving nasal septal anesthesia. **B,** Proper location for administering nasal septal anesthesia.

- 2. Cotton-tipped applicators with 4% cocaine solution are used to paint the nasal mucosa. Leave in place for 5 minutes. This may be contraindicated in patients with cardiac disease.
- Perform bilateral infraorbital nerve blocks, extraoral technique (see earlier).
- 4. Infiltrate the skin along the base of the nares, and continue as subcutaneous infiltration up the nasal-facial crease.
- 5. Inject the septal mucosa with local anesthetic containing vaso-constrictor to help decrease bleeding, especially in nasal or septal fractures. Use 1½-inch needle and inject from posterior to anterior. Now inject subperiosteally between the nasal bones and the tissue, and along the lateral nasal region.

# **CPT/BILLING CODE**

64400 Injection, anesthetic agent; trigeminal nerve, any division or branch

# TOPICAL ANESTHESIA

Suraj Achar • Jonathan Chan

Topical anesthesia offers patients an alternative to local injectable anesthetics. The ideal topical anesthetic should provide 100% anesthesia with rapid onset of action, have prolonged duration, and have no local or systemic side effects. To date, the perfect topical agent has not been developed. New formulations have improved efficacy and application options. (Also see Chapter 4, Local Anesthesia; Chapter 229, Transcutaneous Electrical Nerve Stimulation, Phonophoresis, and Iontophoresis; and Chapter 5, Local and Topical Anesthetic Complications.)

There are many benefits and some drawbacks of topical anesthetics compared with local injectable anesthetics. First, application of topical anesthetics is painless. In addition, topical anesthetics do not distort wound margins in laceration repairs. One drawback is the extra time required to achieve effective anesthetic effect.

Although the first topical anesthetics were developed in the latter half of the 19th century with the first uses of topical cocaine, safer and more effective agents have more recently become available. The use of TAC (tetracaine, adrenalin, cocaine), one of the first topical anesthetic creams to be developed, is no longer supported by the literature. LET/LAT (lidocaine, epinephrine/adrenalin, tetracaine) solution-gel has been found to be equally efficacious as TAC. LET eliminates cocaine (thus lessening the risk for toxicity and seizures), avoids documentation issues, and lowers the cost.

EMLA (eutectic mixture of local anesthetics), which was approved by the U.S. Food and Drug Administration (FDA) in 1992, is now commonly used. A *eutectic mixture* is one in which the melting point of the mixture is lower than that of the individual components; in the case of EMLA, the components (lidocaine and prilocaine) remain liquid at room temperature. LMX 4 (4% liposomal lidocaine) and LMX 5 (5% liposomal lidocaine) are liposomal agents that are available over the counter. LMX 4 and LMX 5 were formerly called ELA-Max. Liposomes are synthetic biologic membranes composed of an aqueous core surrounded by a lipid layer. This delivery system allows medications to penetrate the stratum corneum more readily because they resemble cell membranes, thus strengthening the onset of action while controlling release of the action drug for a longer duration of action.

More recently, the S-Caine Patch has been developed. This 1:1 eutectic mixture of 70 mg lidocaine and 70 mg tetracaine base has a disposable, oxygen-activated heating element. The heat is maintained at 39° C to 41° C for a 2-hour period. Heat has been shown to enhance the delivery of topical creams.

Categories of topical anesthetics can be divided into those applied on intact skin, nonintact skin, and mucous membranes. This categorization is important because a topical anesthetic (e.g., lidocaine) applied to the mucous membrane may result in blood levels comparable with those achieved with parenteral administration (Table 10-1). Available topical anesthetics for intact skin are EMLA/EMLA Disc, LMX 4, LMX 5, and iontophoretic preparations. Also,

with the development of many new aesthetic procedures, many clinicians now have various mixtures compounded (see later, as well as Chapter 59, Skin Peels).

In addition to creams and ointments, cooling can also be used to provide brief, temporary anesthesia (e.g., ethyl chloride spray or ice cubes).

#### **INDICATIONS**

#### **Intact Skin**

#### LMX 4/LMX 5

- FDA: temporary relief of pain associated with minor cuts, abrasions, minor burns, skin irritation, and insect bites.
- Literature-supported uses: venipuncture, venous cannulation, arterial puncture, suture removal, shave biopsy, punch biopsy, chemical peels, curettage of molluscum contagiosum, cryotherapy of venereal warts, intracutaneous allergy testing, epilation, débridement of otitis media with an intact tympanic membrane, removal of an embedded foreign body, circumcision at more than a 37-week gestation, skin grafting, débridement of ulcers, lumbar puncture.
- Adjunct to: vasectomy, dermabrasion, laser resurfacing, postsurgical discomfort.
- Nonsurgical uses: postherpetic neuralgia, meralgia paresthetica.
- Used for intact skin. Efficacy is similar to EMLA, but LMX 4 is less expensive than EMLA.

#### **EMLA**

FDA: for use on intact skin for local anesthesia.

#### Lidoderm Patch

FDA: relief of pain associated with postherpetic neuralgia.

# BLT Triple Anesthetic Gel (20% Benzocaine, 6% Lidocaine, 4% Tetracaine)

- Used for intact skin.
- Percentages may vary.
- This is usually compounded.

# S-Caine Patch/S-Caine Peel

- Used for intact skin.
- Approved for children 3 years of age or older.

#### **Nonintact Skin**

# Topicaine (4% or 5% Lidocaine Gel)

- Minor skin cuts or abrasions.
- Available over the counter.

TABLE 10-1 Summa	Summary of Topical Anesthetics					
Agents	Concentration	Status	Maximum Dose or Area*	Onset of Action	Duration	Pregnancy Category
Intact Skin EMLA cream or anesthetic disc	2.5% lidocaine/2.5% prilocaine	ž	20 g/200 cm² for 7–12 yr of age and >20 kg (A)	60-120 min	180 min	В

EMLA, eutectic mixture of local anesthetics; LAT, lidocaine, adrenalin, tetracaine; LET, lidocaine, epinephrine, tetracaine; OTC, over the counter; Rx, prescription; TAC, tetracaine, adrenalin, cocaine. \*A, Adults; C, children.

<sup>†</sup>Pregnancy of egony 2. Animal studies have not shown a fetal risk but there are no controlled studies in pregnant women. Pregnancy category C: Animal studies are not available. Safety for use during pregnancy has not been established. Use only when potential benefits outweigh potential hazards to the fetus.

†No clinical studies.

†C-II: Controlled substances schedule II drug (Controlled Substances Act of 1970). Cocaine must be stored in a locked cabinet; and separate written records must be maintained for a period of 2 years after the drug is dispensed. Adapted from Huang W, Vidimos A: Topical anesthetics in dermatology. J Am Acad Dermatol 43:286–298, 2000.

### LET/LAT (Lidocaine, Epinephrine/Adrenalin, Tetracaine)

- Scalp and facial lacerations.
- Does not work on intact skin.

#### **Mucous Membranes**

#### Lidocaine (Xylocaine), Benzocaine

- Painful, irritated, inflamed mucous membranes: anesthesia before minor surgical procedure and esophagogastroduodenoscopy.
- 2% viscous lidocaine for aphthous ulcers and mucositis in immunosuppressed patients.

# **Ophthalmic Preparations**

Removal of foreign bodies, short eyelid procedures (e.g., chalazion removal), and placement of eye shields.

#### **Mechanical Methods**

### Thermal: Ice/Ethyl Chloride Spray

Skin tag clipping, incision and drainage of simple abscess, and injections (blood draws, skin grafting, sports injuries).

#### For Aesthetic Procedures

Many noninvasive aesthetic procedures (e.g., deep skin peels, facial resurfacing) require some type of topical anesthetic. Oral analgesic medications and anxiolytics can also be beneficial. Everyone seems to have his or her own favorite compounded preparation. With the rapid growth of procedures in this field, few studies have been published to compare the various combinations and their efficacy.

#### BLT (Benzocaine, Lidocaine, Tetracaine)

BLT is a favorite compounded mixture. The percentages may vary (e.g., 20%, 7%, 7%, or 20%, 6%, 4%). With most BLT preparations, it takes 45 to 60 minutes to obtain good effect.

#### Quadri-Caine

Quadri-Caine (Scripts Pharmacy, St. Joseph, Mich) is a compounded topical anesthetic that has a more rapid onset (10 to 15 minutes). Standard Quadri-Caine consists of 10% lidocaine, 5% tetracaine, 5% prilocaine, and 1% bupivacaine in an emollient cream plus a penetration enhancer. Quadri-Caine VC contains the vasoconstrictor phenylephrine.

Quadri-Caine, as with most of these potent compounded preparations, should be used only under the direction of physicians experienced in the use of high-potency topical anesthetics. It is unknown what amounts of the topical anesthetics in Quadri-Caine reach the systemic circulation. The amount to apply must be determined on a case-by-case basis. It is recommended that not more than 3 g of Quadri-Caine be applied in 24 hours.

Quadri-Caine is not for resale. It must be purchased by a medical office or clinic for use during a patient visit or may be ordered by prescription specifically for individual patient use.

Quadri-Caine and Quadri-Caine VC are registered trademarks and, as compounded products, have not undergone FDA review.

**NOTE:** Compounded products are not produced under the same standards as FDA-approved products. The levels of lidocaine may vary dramatically, and toxicity studies using moderate or large amounts of compounded products have not been performed.

# **CONTRAINDICATIONS**

Many preparations contain preservatives that can cause allergic reactions. If a patient develops an allergic dermatitis while using a

topical anesthetic, he or she may not be allergic to the active drug itself, but rather to other components in the cream or ointment. An allergy to lidocaine is extremely rare, if it occurs at all.

#### LET/LAT

Sensitivity to tetracaine, epinephrine, or lidocaine

#### **EMLA**

- Advanced liver disease (hepatic metabolism)
- Methemoglobinemia risk

#### LMX 4/LMX 5

- Sensitivity to lidocaine.
- Avoid mucous membranes: absorption increases toxicity risks.
- Efficacy diminishes as the skin thickness (lack of absorption) and vascularity (rapid clearance) increases. Essentially ineffective on the palms and soles even if occluded for hours.

#### Lidoderm 5% Patch

- Sensitivity to lidocaine (rare); denuded skin; mucous membranes.
- Do not use more than 12 hours out of 24-hour period to avoid toxicity. Do not use with methemoglobinemia-inducing agents on infants younger than 12 months of age (Box 10-1).
- Use with caution in infants younger than 3 months of age (maximum dose of 1 g for 1-hour application if term).

# **BLT Triple Anesthetic Gel**

- Allergy to p-aminobenzoic acid (PABA), hair dyes, and sulfonamides
- Sensitivity to benzocaine, lidocaine, or tetracaine

#### S-Caine Patch/S-Caine Peel

Sensitivity to lidocaine or tetracaine

# Topicaine (4% to 5% Lidocaine Gel)

Sensitivity to lidocaine

# Box 10-1. Agents Associated with Methemoglobinemia\*

Acetaminophen Nitroprusside Acetanilid Pamaquine Aniline dyes Para-aminosalicylic acid Benzocaine Phenacetin Chloroquine Phenobarbital Dapsone Phenytoin Naphthalene Primaquine Nitrates and nitrites Quinine Nitrofurantoin Sulfonamides Nitroglycerin

From Huang W, Vidimos A: Topical anesthetics in dermatology. J Am Acad Dermatol 43:286–298, 2000.

<sup>\*</sup>Use with caution with eutectic mixture of local anesthetics (EMLA).

# Thermal: Ice/Ethyl Chloride Spray

- Raynaud's phenomenon, cryoglobulinemia
- Not effective for skin biopsy, alters specimen

# Lidocaine (Xylocaine), Benzocaine (Mucous Membranes)

· Sensitivity to Xylocaine or benzocaine

# **Ophthalmic Preparations**

- Not to be used to control pain over long term
- Inhibits healing and, because no sensation, may lead to inadvertent trauma
- May also eliminate blinking, leading to drying of cornea

# **TECHNIQUE**

NOTE: Precautions must be taken to avoid high blood levels of anesthetics. This is especially true with the use of compounded products or FDA-approved products used under occlusion. Part of the confusion that providers face relates to the need to use occlusion with EMLA because of its poor penetration through the stratum corneum. With LMX 4/LMX 5, occlusion is not needed because the liposomes appear to enhance absorption. However, physicians may accidently or purposely use these newer agents under occlusion. Small doses of these drugs have been shown to be safe when used with occlusion, but large doses (>60 g) may be toxic.

#### LET/LAT

Apply 1.5 to 3.0 mL of LET to a soaked gauze and wipe in and over a facial or scalp laceration. Avoid mucous membranes and endarteriolar parts of the body such as the digits. Contact with wound should be a minimum of 10 minutes and a maximum of 30 minutes. Watch for blanching, which correlates with anesthesia. Onset of action is 15 to 30 minutes.

# **EMLA/EMLA Disc**

EMLA cream is a eutectic mixture of 2.5% lidocaine and 2.5% prilocaine. A eutectic mixture is one that melts at a lower temperature than does any of its ingredients. Therefore, both anesthetics exist in a liquid form.

Remove oil from skin with an alcohol or acetone swab. Consider thinning the stratum corneum through tape stripping of superficial cells. Apply the disc or 1 to 2 g per 10 cm² of the cream. Cover with an occlusive dressing (Tegaderm, OpSite, or Band-Aid) for 60 minutes for a 3-mm depth. Every additional 30 minutes provide 1 mm of more depth; a 2-hour maximum time is equivalent to 5 mm. Cream should still be visible when the dressing is removed. If it is not visible, an inadequate amount was used (Table 10-2).

TABLE 10-2 Recommended Maximum Dose and Application Area of Eutectic Mixture of Local Anesthetics

Age	Body Weight (kg)	Maximum Total Dose and Time	Maximum Application Area (cm²)
1-3 mo	<5	lg(lhr)	10
4-12 mo	>5	2 g (4 hr)	20
I-6 yr	>10	10 g (4 hr)	100
7–12 yr	>20	20 g (4 hr)	200

Adapted from Huang W, Vidimos A: Topical anesthetics in dermatology. J Am Acad Dermatol 43:286–298, 2000.

#### LMX 4/LMX 5

Apply for 15 to 40 minutes without occlusion. A transient erythema may develop, but no serious side effects have been observed. In children weighing less than 20 kg, apply cream to an area no larger than 100 cm<sup>2</sup> to prevent systemic toxicity.

#### Lidoderm 5% Patch

Apply up to three patches at one time to cover the most painful area (e.g., postherpetic neuralgia) for a maximum of 12 hours in a 24-hour period. Patches may be cut to smaller sizes for smaller lesions or impaired elimination (e.g., hepatic disease).

# **BLT Triple Anesthetic Gel**

Apply to intact skin for 10 to 30 minutes. Recent studies note that BLT provides effective analgesia after 15 minutes of application.

# S-Caine Patch/S-Caine Peel

Apply S-Caine Patch and use disposable heating element as instructed. Time to effect is 20 to 30 minutes.

Apply S-Caine Peel to area. The cream dries on exposure to air and becomes flexible and is peeled off skin after 20 to 30 minutes. The advantage of this flexible membrane is delivery of topical anesthetic to contoured areas of the body. Do not leave on longer than 30 minutes.

# **Topicaine**

Apply a moderately thick layer (about 1/8 inch) to affected area. Best anesthetic results occur in 20 minutes to 1 hour.

# Lidocaine (Xylocaine), Benzocaine (Mucous Membranes)

Wolfe and colleagues reported in 2000 that atomized lidocaine 4% solution decreased the discomfort of nasogastric tube placement. The combination of 1.5 mL atomized lidocaine applied intranasally plus 3.0 mL applied oropharyngeally plus 5 mL 2% lidocaine jelly applied intranasally is superior to jelly alone. Caution should be used because of impaired swallowing after use. Patients should expectorate excess anesthetic to avoid systemic absorption and toxicity. Plasma levels are similar to those obtained with intravenous injection. For viscous solution, do not exceed 1 tablespoon (15 mL) every 3 hours or 1 teaspoon (5 mL) of 5% liquid in an adult (see Chapter 4, Local Anesthesia, and Chapter 5, Local and Topical Anesthetic Complications, for maximum doses). Ingestion of food should be avoided for at least 1 hour after oral use to prevent aspiration.

# Thermal: Ice/Ethyl Chloride Spray

For skin tag clipping hold ice in direct contact for 10 seconds and clip skin tag immediately.

For skin tag clipping or draining an abscess spray the vaporized coolant for 1 to 2 seconds until the dermis turns white and immediately clip the tag or incise and drain the abscess. Use caution because overapplication causes blistering.

#### **Ophthalmic Use**

Apply one or two drops in the eye. The effects of the anesthetic are rapid (30 seconds) and persist up to 15 minutes. An additional drop can be placed every 5 to 10 minutes for a total of 7 to 10 drops.

#### **CONCLUSION**

Topical anesthetics may offer a painless alternative to painful injectable anesthetics. Since the advent of TAC, there have been numerous advances. EMLA cream and over-the-counter LMX are now available. Moreover, advances in delivery modes, including heat in S-Caine Patch and flexible membranes in S-Caine Peel, allow the provider to tailor topical anesthetics to specific clinical situations.

# ACNE THERAPY: SURGICAL AND PHYSICAL APPROACHES

Michael A. Altman

Acne is the most common skin disease of childhood and adolescence and is estimated to affect 80% of individuals between 11 and 30 years of age and up to 95% of all adolescents. It is a disease of the pilosebaceous unit. Acne involves increased sebum production, obstruction of the pilosebaceous glands with keratinization of the canal, bacterial proliferation, and inflammation. Many topical and systemic medications have been developed to treat acne. When these medications fail to control the disease, or when significant lesions develop, several procedures may be used to intervene. This chapter focuses on the procedures a primary care physician might consider in the office treatment of acne.

#### **COMEDO REMOVAL**

The removal of open comedones (blackheads, noninflamed plugged pores) enhances the patient's appearance while preventing the development of inflamed acne lesions and cysts (with their complications). Instruments such as the round loop (or oval loop) extractor (Fig. 11-1) or the Schamberg extractor effectively extract the plug by allowing uniform, smooth pressure to encircle the pore (Fig. 11-2). Downward pressure allows the comedo or pus to exit through the hole in the extractor. Extractors can be obtained from any medical supply provider, and some are even sold over the counter.

Open comedones that offer resistance can be loosened with one of two techniques:

- 1. Application of tretinoin (Retin-A), a topical keratolytic, for 1 month before comedo extraction.
- 2. Use of a no. 11 blade, tip of a needle, or the pointed end of a comedo extractor to stretch the walls or slightly incise the pore opening. The physician should insert the scalpel point 1 mm into the comedo, following the angle of the follicle opening, and angle the tip to bring the plug upward through the enlarged pore opening.

If there is still resistance, the comedo extractor should be held in the other hand and lateral pressure applied with the blunted end to the base of the lesion as the blade lifts the plug through the center of the extractor. A large amount of sebaceous material may be found beneath the plug and should be removed.

# **ACNE SURGERY FOR PUSTULES AND CYSTS**

The surgical drainage of acne pustules and cysts, when performed correctly, speeds resolution of the lesions, prevents subdermal rupture, and enhances cosmetic appearance. Closed comedones can also be opened to prevent their progression to inflammatory lesions.

Enter the head of a white pustule with a small (25-gauge) needle, with the tip (tiny nick) of a no. 11 blade, or the pointed end of the comedo extractor. Drain the pustule with lateral pressure or with the assistance of an extractor. Superficial cysts that have thin roofs

and easily palpated fluid can be drained by making a small incision less than 4 mm long. Some physicians advocate that the base of a drained superficial cyst be gently curetted to dislodge any necrotic debris. Nodules and large cysts may best be treated by intralesional corticosteroid injection.

# INTRALESIONAL CORTICOSTEROID INIECTION

Individual nodular or cystic acne lesions often dramatically decrease in size after intralesional injection of a corticosteroid. It is reassuring to patients to know that a fast, relatively painless procedure is available when lesions arise. Patients with severe acne often require repeated injections every 2 to 3 weeks. Multiple cysts can be treated in one session.

The steroid preparation triamcinolone acetonide 10 mg/mL (e.g., Kenalog-10) is a preferred agent and should be diluted to about 2.5 mg/mL with saline or local anesthetic (e.g., 1% lidocaine). Saline is the preferred diluent because injections of local anesthetics are painful. Triamcinolone acetonide is particularly useful in that it is insoluble and therefore can remain deposited for months at the injection site, achieving its desired local effect without risk for adrenal suppression.

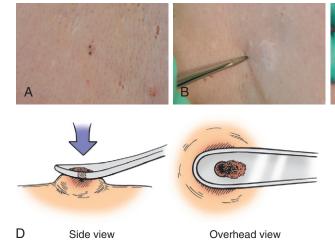

When preparing for an injection, shake the steroid vial to disperse the suspension. First draw the saline into a tuberculin syringe, followed by an appropriate amount of triamcinolone. (If lidocaine is the diluent, use only single-dose vials to prevent precipitation of the steroid.) An air bubble can be aspirated into the syringe to mix the two. Then insert a 30-gauge needle through the thinnest portion of the cyst roof and deliver 0.05 to 0.3 mL of the resulting 2.5-mg/mL triamcinolone acetonide mixture. Limit the maximum volume to 0.2 mL per lesion to reduce the risk of skin atrophy. The injection usually blanches the cyst.

Inject directly into the cyst, not the skin. Skin atrophy can follow injections if the steroid is deposited into the skin below the cyst or if the steroid concentration is too high. One session of injections should not exceed a total of 10 to 20 mg of triamcinolone, to avoid systemic effects. It may be necessary to repeat intralesional injections at 2-week intervals, not to exceed three total sessions.

Fluctuant lesions can be aspirated first with a large-bore needle attached to a 1- or 3-mL syringe before steroid injection. Skin atrophy remains unlikely, but the patient should be forewarned that atrophy still may occur independent of the injection because of

**Figure 11-1** Comedo extractor. Note pointed end and cupped end with central opening.

**Figure 11-2** Use of comedo extractor to express cystic contents. **A,** Comedo. **B,** Incising over comedo to enlarge opening using sharp end of extractor. **C,** Applying pressure over comedo to express contents through central opening of extractor. **D,** Graphic representation of **C**.

underlying inflammation involving the collagen bed. Secondary bacterial infections do not occur. Avoid injecting the periorbital and perinasal areas because steroid crystals inadvertently injected into vessels may drain into the cerebral venous sinuses or central retinal artery. Finally, counsel patients that skin depression may occur, but in most cases it is temporary and gradually resolves in 4 to 6 months.

#### **CRYOTHERAPY**

Cryotherapy has been found to be effective against pustular acne but not against comedonal or papular acne. It is most effective against superficial cystic lesions and least effective against deeper lesions. Any softening effect on scars is usually temporary. Application is painful and burning discomfort may last up to 4 hours. In current dermatology, it has fallen out of general use for acne management.

# **OTHER CURRENT APPROACHES**

Photodynamic therapy (see Chapter 60, Photodynamic Therapy), microdermabrasion (see Chapter 58, Microdermabrasion and Dermalinfusion), and chemical peels (see Chapter 59, Skin Peels) can also be used to control acne by physical techniques.

#### **SCAR REVISION**

- 1. A variety of procedures can be used to remove or revise acne scars. Deep, "ice-pick" scars can be excised using a punch biopsy and immediately replacing the scar plug with a full-thickness punch graft of normal skin. This procedure is relegated to early scar revision now that laser skin resurfacing is available.
- 2. Another technique, punch-graft elevation, uses a punch just slightly larger than the pitted scar. A cylindrical incision is made into the dermis, allowing the core to "pop out" above the skin surface. A Steri-Strip secures this skin core just above the surrounding skin. Dermabrasion of the remaining treatment site may be required at a later date. Results are unpredictable.
- 3. Collagen injections can be used to smooth the skin surface, but are a temporary solution (see Chapter 57, Tissue Filler).
- 4. Dermabrasion involves the use of a high-speed hand drill with a diamond-studded steel sander under local anesthesia to smooth out scars. Microdermabrasion (see Chapter 58, Microdermabrasion and Dermalinfusion) can also be used. It is less aggressive and there is little recovery time, but many (six to eight) visits may be needed. It is best reserved for more superficial scars.

- 5. The latest carbon dioxide laser methods use a fractionated column of light to smooth the skin (e.g., Active FX and Fraxel). This affords less "down time" because it is less aggressive than previous laser treatments. At the same time, it can smooth the skin more effectively and with fewer treatments than microdermabrasion or chemical peels.
- 6. Scar revisions should not be performed for 6 months to 1 year after use of oral isotretinoin.

#### **COMPLICATIONS**

Complications include adverse pigmentary changes, deeper and longer scars, and increased skin sensitivity to sunlight.

# APPROACH TO VARIOUS SKIN LESIONS

John L. Pfenninger

This chapter provides guidelines for the diagnosis and treatment of common skin lesions. Table 12-1 can be used as a guide for proper biopsy and treatment techniques. The specifics of performing the procedures are reviewed elsewhere in this textbook. These guidelines are not intended to be all-inclusive, but they do provide a framework for the approach to common skin lesions.

All excised skin lesions are best sent to the pathologist for definitive diagnosis. With selected lesions, such as skin tags or sebaceous cysts, many physicians will rely on their clinical judgment and avoid the added laboratory expense. However, in today's litigious society, the physician must be absolutely certain of the diagnosis when deciding not to send tissue to the pathologist for evaluation. Numerous benign lesions can be placed in a single formalin container (e.g., skin tags, obviously benign nevi) to cover the legal aspects and yet conserve costs. The fee to process each bottle (regardless of the number of samples in it) is approximately \$160 to \$200 for the routine dermatologic lesion.

# ANGIOMA (HEMANGIOMA)

If the angiomas are small, use a ball electrode to cauterize them lightly. If larger than 2 mm, local anesthesia may be needed. Tissue should be wiped away and the process repeated until no vessel is seen (Fig. 12-1). Focal cryotherapy or sclerotherapy will also work. If the angiomas are large, a superficial shave excision or curettement followed by light cautery of the base works best.

# **ACROCHORDON (SKIN TAG)**

Although many physicians prefer to use electrosurgery or cryotherapy to remove acrochordons, the most direct and simple approach is to elevate the tag with pickups and excise it with sharp tissue scissors at the level of the surrounding skin (Fig. 12-2). If it has a broad base, a local anesthetic may be required. Monsel's solution (ferric subsulfate) or aluminum chloride may be used for hemostasis. It is essential to have good-quality scissors so the lesion is cut, not "pinched."

If the tag is small enough, a ball electrode can be used to lightly and quickly cauterize the tag. It is then simply "wiped away," similar to the treatment of a small angioma (see earlier).

Cryocautery can be effective, but it is difficult to limit the freeze solely to the tag. A unique method with liquid nitrogen is to use the Styrofoam cup method, dipping the flat pickups in the liquid, and then grasping the tag with the cooled metal. The tag usually necroses off. The tag should be frozen twice in the same visit. Special thickened metal forceps are available from Brymill Cryogenic Systems (Ellington, Conn) that stay colder longer and can be used to treat multiple lesions without having to dip into the liquid nitrogen repeatedly (Fig. 12-3).

#### **ACTINIC KERATOSES**

Actinic keratoses (Fig. 12-4) are sun-induced, premalignant lesions. Single lesions can be shaved, cauterized, or, most commonly, treated with cryotherapy. When multiple lesions are present, they can be treated with 5-fluorouracil (5-FU, Efudex), masoprocol (Actinex) cream, imiquimod (Aldara) cream, or photodynamic therapy with δ-aminolevulinic acid (Levulan) in conjunction with light therapy (e.g., blue light, intense pulsed light [IPL]). Lesions that do not resolve require surgical sampling for histology. They are then frequently squamous cell carcinomas (SCCs; see treatment methods, later). The risk that actinic keratoses will progress to SCC is probably less than 1% in early lesions, and as high as 10% to 20% for persistent hypertrophic lesions. The patient should be counseled that both 5-FU and masoprocol cause significant erythema and tenderness in the areas treated. For 5-FU and masoprocol, the medication is applied twice a day for 3 to 4 weeks to the face and three to four times per day on the arms. (See patient education form online at www.expertconsult.com. The manufacturer will also provide a patient education videotape.) Treatment with imiguimod is significantly more expensive, with less efficacy (Table 12-2). Steroid creams may be used to reduce the inflammatory response. Alternatively, daily application of retinoic acid (Retin-A) 0.025% or 0.05% may resolve early lesions and prevent new ones. Protection from the sun is essential.

# **BASAL CELL CARCINOMA**

Basal cell carcinomas (BCCs) characteristically have small, centrally ulcerated depressions and raised, pearly borders (nodular-cystic type; (Fig. 12-5A and B). However, their actual appearance can vary markedly from the classic description. Sclerosing (or morpheaform; Fig. 12-5C) BCCs may manifest as flat lesions with nondescript borders. Others are nonhealing ulcerations that never do become elevated. Some are *pigmented* (Fig. 12-5D) and may be confused with seborrheic keratoses (SKs), nevi, or even melanomas. They may appear erythematous and bleed easily, mimicking a pyogenic granuloma. Superficial (Fig. 12-5E) BCCs commonly occur on the back and are flat and scaly. They may look like an SCC, actinic keratoses, eczema, or even tinea. A biopsy should be taken of all nonhealing, changing, or enlarging skin lesions. Once a diagnosis is made, proper treatment can be planned. Chronic sun exposure, chronic irritation, and the human papillomavirus appear to be the most common causative factors.

When a biopsy is taken of a suspected BCC, almost any area of the lesion is appropriate for sampling. If the lesion is ulcerated, it is best to sample the nonulcerated portion because the ulcer may show only necrotic changes if enough depth is not included in the sample. Normal skin from the margin is *not* needed in the specimen.

#### <sup>a</sup>Procedure of choice.

 $^{\mathrm{b}}\!\mathsf{Face}$  only; legs require sclerotherapy or laser. Extremely fine veins may require IPL or laser.

Imiquimod (Aldara), podofilox (Condylox), interferon; see Chapter 155, Treatment of Noncervical Condylomata Acuminata.

If used here, must be sure to use deep, saucer-shaped shave and that entire lesion removed in initial sample (do not use if suspect melanoma).

Candida antigen; bleomycin, imiquimod (Aldara), see Chapter 42, Wart (Verruca) Treatment.

<sup>I</sup>Generally not indicated unless large, recurrent, or severely dysplastic.

PIPL, scleropathy.

Figure 12-1 A, Hemangioma. B, Cautery of hemangioma. C, Hemangioma after cautery.

<sup>&</sup>lt;sup>d</sup>Used only if cancer is a possibility or nature of lesion unknown.

<sup>&</sup>lt;sup>e</sup>Not approved by the Food and Drug Administration.

Followed by cautery and curettement.

<sup>&</sup>lt;sup>g</sup>Preceded by shave removal.

<sup>&</sup>lt;sup>h</sup>Use only if certain that lesion is not a melanoma.

<sup>&</sup>lt;sup>k</sup>Retin-A.

<sup>&</sup>lt;sup>m</sup>See Table 12-3.

 $<sup>{\</sup>rm ^nRadiation}$  generally reserved for large, unresectable or recurrent lesions.

<sup>°</sup>Levulan plus IPL/light therapy.

<b>TABLE 12-2</b>	Comparison of Costs for Topica	ı
Treatment of	of Actinic Keratoses	

Agent and Preparation	Treatment Regimen	Cost of One Treatment
δ-Aminolevulinic acid (Levulan), 20% sol	+ Blue light or intense pulsed light	\$108.02+
Diclofenac (Solaraze), 3% gel	Twice daily for 60–90 days	\$105.00
5-Fluorouracil (generic), 2% solution	Twice daily for 2–4 wk	\$51.40
5-Fluorouracil (generic), 5% solution	Same	\$74.50
5-Fluorouracil (Efudex)	-	
5% cream	Same	\$102.25
2% solution	Same	\$69.70
5% solution	Same	\$102.90
5-Fluorouracil (Fluoroplex), 1% cream	Twice daily for 2–6 wk	\$80.40
5-Fluorouracil (Carac), 0.5% cream	Once daily (max. 4 wk)	\$98.10
Imiquimod (Aldara), 5% cream	Twice weekly for 16 wk	\$518.76

Prices have increased significantly since 2004. The cost to the patient for one tube of Efudex 5% cream (40 g) on March 17, 2009 was \$342.00, while the generic was \$257.00 (Rite-Aid, Midland, Mich.)

From Imiquimod (Aldara) for actinic keratoses. Med Lett Drugs Ther 46:42–44, 2004.

**Figure 12-6** Electrodesiccation and curettage for a basal cell carcinoma. Sequence is repeated a total of three times. **A,** Dermal curette (available as disposable and reusable). Generally, for cancers, the reusable curettes are used because they are not as sharp and are less likely to penetrate the dermis. **B,** Lesion is curetted away. This tissue is sent to pathology for histologic diagnosis. **C,** Cautery of curetted area.

Figure 12-5 Basal cell carcinoma. A, Nodular; B, nodular ulcerative; C, morpheaform; D, pigmented; E, superficial.

The treatment of BCCs is rather straightforward. No one dies from BCCs unless there is long-term total neglect, and they almost never metastasize, so failure of treatment will generally lead only to recurrence, which then may need referral or more aggressive treatment. They can be difficult to treat, with higher recurrence rates in the nasolabial folds and the preauricular areas. The inner canthal area can be an especially difficult area to excise and treat because of tear duct involvement. Careful follow-up is needed to detect early recurrences. Any lesion that is less than 5 to 6 mm in any location generally has an excellent response to almost any treatment modality.

There are many approaches to the treatment of BCCs. Radiation therapy is rarely used, but it may be necessary when the lesions are located in areas such as the lid margins, and in large lesions found on elderly patients. It is usually not recommended for sclerotic/morpheaform types, around the tear ducts where there can be scarring, or in young people when there can be long-term sequelae from the radiation.

BCCs usually involve the upper portions of the skin and, again, very rarely metastasize. Deaths are extremely rare and reportable. For the majority of lesions that are smaller than 1 cm, treatment with cautery and curettement (electrodesiccation and curettage [ED&C]) is a rapid and effective solution. Cure rates approach 95% to 98%, and scarring is usually minimal (Figs. 12-6 and 12-7). The technique is as follows:

- 1. After local anesthesia, scoop out the lesion with a large reusable dermal curette. The disposable units are too sharp for this procedure. Scrape the base of the lesion until a gritty feeling is encountered. Usually, it is rather easy to determine when all of the soft necrotic tissue is removed. If the lesion has not been previously sampled, send this first curettement to pathology. (Do not include tissue that is obtained after the cautery; see Fig. 12-7B.)
- 2. Then fulgurate or cauterize the entire base with a ball electrode to destroy remaining cells and control bleeding.
- After the first cauterization, again vigorously curette the site to remove any of the char. Scrape until "grittiness" is palpable once again.
- 4. Perform fulguration or cauterization a second time, as before.
- 5. Carry out the third and final curettement with a smaller dermal curette that more easily enters any tiny crevices in the wound site. Be careful not to penetrate too deeply and pass through the entire dermis. If this should happen, a small window of fatty

- tissue will be visible in the bottom of the wound, and formal excision is indicated because the tumor most likely went deep into the subcutaneous tissue.
- 6. After the third curettement, fulgurate or cauterize the lesion for the final time. Place some topical astringent, a small amount of antibiotic ointment, and a dressing. Although the wound appears significantly ulcerated at this point, the long-term cosmetic results of this procedure are excellent if patients follow *moist* healing practices (see the sample patient education form available online at www.expertconsult.com).

Encourage the patient to *gently* wash the area three or four times a day with soap and water to prevent an eschar from forming. Immediately after washing, have the patient apply an antibiotic ointment to keep the area moist. The ointment can be applied six or eight times a day, not so much to prevent infection but to aid the reepithelialization of the wound. Petroleum jelly may work as well. Allow the wound to be open unless it is under clothing. Cover it at night if necessary to keep it moist.

Lesions in younger patients, larger-sized (>1 cm) lesions, lesions in more aggressive locations (nasolabial folds, preauricular areas, eyelids), sclerosing-type BCC lesions, recurrent lesions, and lesions with ill-defined margins may require complete excision to enable the pathologist to examine the margins. Remove 3 to 4 mm of normal skin around all edges (Table 12-3). Margins can be marked to aid in the histologic evaluation. Some physicians believe that excision is more cosmetically acceptable than cautery and curettement. An advantage of ED&C over cryotherapy is that the necrotic lesion can be "felt" with the curette, so the surgeon knows how far and deep to proceed with the scraping. If properly cared for, most lesions treated with ED&C will only have some mild depigmentation after 4 to 6 months. Although cryotherapy reportedly is very successful, the surgeon cannot often "feel" or see the margins of the tumor. All the various clinical factors should be weighed when selecting the method for lesion removal.

Laser therapy can be used to ablate the lesions. Topical 5-FU and imiquimod have been approved to treat superficial BCCs. Cryotherapy has excellent results for lesions less than 1 cm wide. A good freeze 5 mm past the lesion is required, followed by thawing, then a repeat freeze (see Chapter 14, Cryosurgery). It is critical to note the thaw time. Cure rates of 98% are reported (see caveat previously).

Follow-up 3 months after treatment to ensure success of treatment is recommended. The patient must be followed closely because

**Figure 12-7 A,** Basal cell carcinoma of right nose. **B,** After administration of local anesthetic, the lesion is curetted. **C,** Cautery of the base with a ball electrode. Repeat curettement and cautery for a total of three times. **D,** Appearance of wound after completion of treatment. (Courtesy of The Medical Procedures Center P.C., Midland, Mich.)

TABLE 12-3	Excisional	<b>Margins</b>	of	Normal	Tissue
for Various	Skin Lesion	ıs			

Lesion	Margins
Atypical nevi

In situ	5 mm
Invasive to 1 mm (no ulceration, low mitotic count)	l cm
>1 mm depth of invasion or ulcerated, increased mitotic count	Refer

30% of patients will develop new BCCs somewhere within 3 years (Table 12-4).

Mohs chemosurgery is not indicated for routine treatment of BCCs. Consider it for recurrent, morpheaform-type, or very large lesions. It may also be used for larger lesions in high-risk sites. The cost does not justify routine use because cure rates are so good with the other methods discussed here.

# **SQUAMOUS CELL CARCINOMA**

Squamous cell carcinoma (Fig. 12-8) often appears as a diffuse, nonhealing, crusted lesion. It frequently occurs at the base of an actinic keratosis or cutaneous lesion. The lesions may be multifocal in origin and, as with actinic lesions, are due to solar damage. SCCs are more aggressive than BCCs and can metastasize. Because the margins of these lesions are often not very clear, many clinicians prefer to excise all invasive SCCs. If 5-FU (Efudex) or masoprocol (Actinex) creams or cryotherapy are used to treat diffuse actinic changes, any post-treatment residual lesions (after 6 to 8 weeks) should be removed for biopsy to rule out SCC. When a biopsy is performed on a suspected SCC, try to include portions of the central area. A deep punch biopsy into subcutaneous fat is preferred by many pathologists, but a deep saucer-type shave is adequate, with definitive therapy after pathology results. Early or small lesions can be treated with cautery and curettement (see Figs. 12-6 and 12-7) or with cryotherapy, with excellent results (see earlier). If the lesion

**TABLE 12-4** Follow-up of Various Skin Cancers after Treatment (Nonmetastatic)

Cancer	Follow-up
Basal cell carcinoma Squamous cell carcinoma Melanoma	3 mo, 6 mo-I yr Every 4-6 mo (2-3 times) first year Every 6 mo (2 times) second year Every I yr lifetime (First-degree family members should be examined and counseled. Stress sun avoidance/protection.)

Figure 12-8 Squamous cell carcinoma.

is excised, remove at least 5 mm of normal tissue to be sure all margins are clear (see Table 12-3).

SCC in situ (Bowen's disease) is a severely dysplastic lesion that has not yet invaded beyond the epidermis. This lesion should be treated similarly to SCC, although excision is rarely needed.

Lesions (especially the more invasive ones) should be reevaluated in 3 and 6 months to document cure. Evaluation of the lymph nodes draining the area is also prudent (see Table 12-4).

Coding for skin cancer treatment is complicated. The biller must know the size, location, and method of removal to bill correctly.

#### **CONDYLOMATA ACUMINATA**

Many therapeutic interventions are available to treat condylomata acuminata. See Chapter 155, Treatment of Noncervical Condylomata Acuminata.

#### **DERMATOFIBROMA**

Dermatofibromas (Fig. 12-9) often occur on the anterior surface of the lower leg. The etiology is unknown, but dermatofibromas may represent a fibrous reaction to trauma, viral infection, or insect bites. They are often confused with verrucae or nevi. Dermatofibromas do not progress to cancers, and once the diagnosis of dermatofibroma is confirmed, the physician often can merely observe the lesion. However, until the lesion is sampled, only an educated guess is possible. Many BCCs of the lower extremities mimic dermatofibromas. A rapidly growing lesion could be a dermatofibrosarcoma. Dermatofibromas are generally deep-seated and require excision if complete removal is desired. Cryotherapy can be attempted but dermatofibromas are generally quite cryoresistant. Because the lesions are often on the legs and are cut while shaving, the most judicious approach is to shave the lesion flat, which provides tissue for confirmatory diagnosis

Figure 12-9 Dermatofibroma.

Figure 12-10 Cutaneous horn.

and reduces the likelihood of further trauma. A pigmented spot may remain, but at least it will be flat. If final results are not satisfactory, it can still be excised or cryotherapy can then be attempted.

# **CUTANEOUS HORN**

A cutaneous horn (Fig. 12-10) is a type of actinic keratosis. Use caution to rule out an early SCC at the base. Usually a deep saucer-type shave is performed, followed by cautery. Tissue should be sent to pathology for verification.

#### **KERATOACANTHOMA**

Keratoacanthoma (Fig. 12-11) is a common, "benign" epithelial tumor found in elderly patients. This lesion may have a viral etiology. Keratoacanthoma often is confused with SCC, but it is a distinct entity and often considered an "SCC variant" because it cannot be differentiated histologically from SCC. The history of rapid growth is critical for the pathologist to make the proper diagnosis.

The lesion begins as a dome-shaped papule that continues to enlarge rapidly. A fully developed tumor is a round, dome-shaped mass with a central keratin-filled crater often 1 to 2 cm in size. The lesion may stop growing after 6 weeks, and then it may slowly regress over the next 12 months. These lesions often occur on the dorsum of the hands, ears, and neck. Clinically they often appear to be

Figure 12-12 Seborrheic keratoses.

BCCs, but if curettement is attempted they are much more sclerotic and fibrous, unlike the classic BCC.

Because these lesions grow rapidly, most physicians do not advocate simple observation. Cryotherapy (small lesions only), a deep saucer-type shave, ED&C (×3), or conventional excision with 3- to 5-mm free margins provides acceptable treatment. Keratoacanthomas can recur, and patients should be followed closely during and after treatment. The major differential diagnoses for the clinician include BCC and SCC. Because of the rapid growth and high numbers of mitotic cells, even pathologists experience difficulty and often will report that they "cannot rule out SCC" at the base. Subsequently, the therapeutic approach is essentially the same as for an SCC.

#### **SEBORRHEIC KERATOSES**

Seborrheic keratoses (Fig. 12-12) are benign, hyperkeratinized, superficial epidermal lesions that occur commonly with aging. Their size ranges from 2 mm to 3 cm. They have no malignant potential. The typical lesion has the appearance that it can be easily lifted off with a fingernail. Patients often say that they have removed the lesion or rubbed it off with a towel, only to have it recur. SKs are occasionally confused with BCCs, SCCs, nevi, and verrucous lesions. Pathology reports often use the term *verruciform keratosis*.

Most SKs can be easily removed, after anesthesia, with the *radiofrequency* (electrosurgery) *shave* technique. Alternatively, *shave excision with mild curetting* of the base can be performed. Hemostasis can be accomplished with Monsel's solution or aluminum chloride. Minimal scarring should result because the lesion is so superficial.

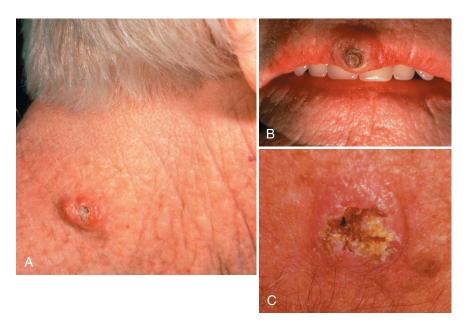

Figure 12-11 A-C, Keratoacanthomas.

Figure 12-13 Lentigo.

Cryotherapy is the most frequently used method. No anesthesia is needed, but this treatment may cause a little more discomfort. Liquid nitrogen is the quickest approach, especially if multiple lesions are present (use the spray thermos applicators). After treatment, a blister may form or the lesion may just dry up and fall off. It is essential that the clinician be absolutely sure of the diagnosis if cryotherapy is to be used. Any lesions that persist need to be sampled. If many SKs occur all at once, consider an internal malignancy (Leser-Trélat sign).

Medicare does not reimburse for removal of SKs unless they are markedly irritated or pruritic, bleeding, or rapidly growing, or if the diagnosis is uncertain.

#### **LENTIGO**

Lentigos (Fig. 12-13), or liver spots, are common, brownish or tan macules that occur on the sun-exposed areas of the face, shoulders, arms, and hands. They are often called "senior freckles." Lentigos increase in number during childhood and adult life and occasionally they fade spontaneously. Biopsy of lesions with irregular borders or dark pigmentation should be performed to rule out lentigo maligna melanoma. Cryotherapy is the treatment of choice. Although bleaching and depigmenting creams may be tried, they will need to be used lifelong. Superficial ablation techniques with laser, radiofrequency, or trichloroacetic acid also may work. The latest, most effective approach is to use IPL, but the technology is expensive (see Chapter 53, Fractional Laser Skin Resurfacing).

# LENTIGO MALIGNA (MELANOMA IN SITU)

Lentigo maligna is a sun-associated precursor of lentigo maligna melanoma, a type of invasive melanoma. These lesions can grow to be several centimeters in diameter and usually occur on the face. They are slow-growing macules with irregular borders and pigmentation. These lesions often are confused with "liver spots" (lentigos), which are smaller, have a homogeneous color, and appear mainly over the dorsa of the hands and forearms. The estimated lifetime risk of transformation from lentigo maligna to melanoma is only 4.7%, and some physicians prefer close observation as the treatment of choice. Unless absolutely sure of the diagnosis, a biopsy should be done. Removal is probably best done with complete surgical excision.

# **LIPOMAS**

Lipomas (Fig. 12-14) present as a palpable mass under the skin. Most lesions are nontender, move freely, and have a soft, irregular consistency. The differential is usually a sebaceous cyst. Cysts have pores; lipomas do not. Cysts are more tense. Lipomas usually do not progress to malignancy, but rapidly growing or changing lesions should be removed to rule out liposarcoma. Removal also may be necessary when lipomas occur in areas of pressure or when they cause pain or discomfort. Lesions on the lower extremities have a higher likelihood of malignant degeneration. Lesions up to 3 cm are removed by making a 1- to 2-cm incision through the dermis after

Figure 12-14 Arm with multiple lipomas.

injecting as little as 1 mL of 2% lidocaine with epinephrine. Sterile preparation and draping are not needed. The clinician should make the incision in line with the skin lines and use hemostats or curved tissue scissors to dissect the lesion from the surrounding adhering tissue. Pressure on the base of the lesion often will extrude the lipoma through the small incision (Fig. 12-15). Some lipomas are encapsulated, but more often the margins are obscure. It may be difficult to determine whether all of the lesion has been removed because the fat involved looks just like normal fat. It is best to remove any loosely adhering fatty tissue in the cavity. Bleeding is minimal. Closure usually can be obtained with Steri-Strips or tissue glue, followed by a pressure dressing. Once the diagnosis of lipoma has been made in one area, other similar lesions do not necessarily require removal unless they are symptomatic. (Lesions that are larger than 3 to 4 cm may require formal excision with sterile technique and suture closure.)

There are special CPT codes for removal of these lesions under "Excision of Benign Tumors." The code is independent of the method used for removal (see Appendix G, Neoplasms, Skin: ICD-9 Codes).

# **MELANOMA**

The major caveat regarding melanomas (Fig. 12-16) is that the *depth* of the lesion is very important in determining appropriate definitive treatment. Primary care physicians should not feel uncomfortable about performing a biopsy of any lesion with characteristics that may be consistent with a melanoma. A biopsy does not spread the lesion or limit life expectancy in any way. On the contrary, early diagnosis may save the patient's life. The mnemonic A, B, C, D, E, F, G can be used as an aid for remembering the clinical features of malignant melanoma:

Asymmetry
Border irregularity
Color variegation
Diameter more than 6 mm
Elevation above skin surface
Feeling different (including pruritus); "F" also is a reminder to check family history
Growth or change

Because it is so important to determine the depth of the lesion, never perform a shave biopsy or shave removal if melanoma is a serious consideration (see Chapter 32, Skin Biopsy). When choosing a site for punch or incisional biopsy within a pigmented lesion, choose the area that is most nodular or atypical (darkest in color, inflamed, or irregular). The majority of pigmented lesions removed are atypical nevi. Saucer-type shaves are acceptable for biopsy and removal if the clinical impression is that melanoma is unlikely. The point is, all atypical nevi cannot be excised with suture closure. It is too time consuming and costly. If there is a strong clinical suspicion for melanoma, do a punch biopsy, which provides depth and the information needed for further treatment. However, if the working diagnosis is an atypical nevus, a shave biopsy is adequate. To save lives, atypical lesions need to be sampled, and shave excisions are the most expedient. Some

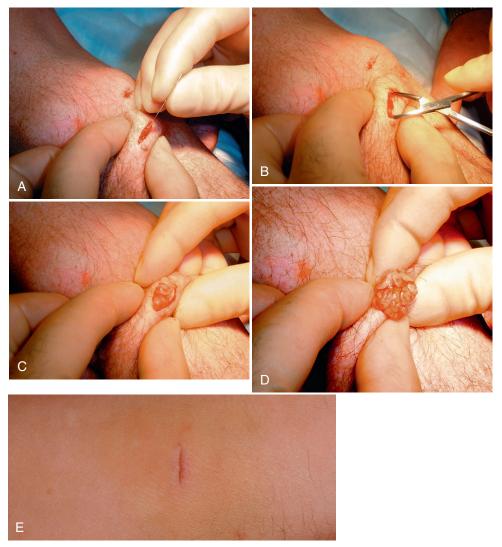

Figure 12-15 Simple technique for removing lipomas. **A**, After local anesthesia is administered, incise and drain the lipoma. **B**, Lysing adhesions with hemostat. **C**, Expressing the lipoma. **D**, Completing removal. Wound is closed with Steri-Strips and pressure dressing applied. **E**, Appearance I week after removal of lipoma using this technique.

unsuspected melanomas may be transected, but at least they will be diagnosed and further care can be initiated.

Recent National Institutes of Health (NIH) guidelines indicate that with lesions that invade less than 1 mm, 1-cm clear excisional margins around the lesion should be adequate for treatment. An extensive work-up for metastases is not indicated for the minimal-depth lesions (Table 12-5).

# **MOLLUSCUM CONTAGIOSUM**

The lesions of molluscum contagiosum (Fig. 12-17) are small, 2- to 3-mm, papular, wartlike excrescences with central umbilication. They are painless and rarely cause pruritus. They usually appear as a crop of multiple lesions in young children, or later in adolescents and young adults as they become sexually active.

Figure 12-16 A-C, Melanomas.

TABLE 12-5 Treatment of Suspect Pigmented Lesions and Melanomas			
Stage	Recommended Treatment	Survival	
Suspect pigmented lesion Suspected positive lymph node with melanoma Early melanoma	Punch, incisional, or excisional biopsy down to subcutaneous fat Fine-needle aspiration biopsy or excision	Not affected by biopsy procedure Not affected by biopsy procedure	
Melanoma in situ (limited to epidermis)	Excision with margin of 0.5 cm normal skin and layer of subcutaneous tissue  No further radiographs or laboratory work indicated	Not affected	
Depth <1 mm	Excision with margin of 1 cm normal skin and subcutaneous tissue down to fascia No further radiographs or laboratory work indicated unless lesion is ulcerated or has high mitotic count	95% (8 yr)	
Intermediate melanoma			
Depth I–4 mm	After diagnostic biopsy, wide-margin excision and adjunctive therapy should be considered (refer)	Poor	
High-risk melanoma			
Depth >4 mm	After diagnostic biopsy, wide-margin excision and adjunctive therapy should be considered (refer)	Poor	

Modified from NIH Consensus Conference: Diagnosis and treatment of early melanoma. JAMA 268:1314-1319, 1992.

Figure 12-17 Molluscum contagiosum.

Expectant observation is certainly acceptable because the lesions will spontaneously resolve (3 to 18 months), but many patients desire to have these viral lesions removed. Table 12-1 describes the treatments that are possible. Curettement with a small disposable (sharp) dermal curette or cryotherapy is the treatment of choice. Treatment rarely requires anesthesia, but topicals can be tried (see Chapter 10, Topical Anesthesia).

# **N**EUROFIBROMAS

Neurofibromas (Fig. 12-18) are soft, nodular lesions that often appear to be minimally pigmented nevi. When a shave excision is performed, however, a soft, jelly-like material is seen at the base. This is the pathognomonic sign of a neurofibroma. The soft tissue is curetted and the base cauterized. A significant cavity may exist, but with moist healing techniques the results are excellent. These lesions do not have to be removed unless symptomatic or if a diagnosis is needed. Excision with suture closure is needed for the larger lesions. Free margins of 1 mm are adequate.

# **PYOGENIC GRANULOMAS**

Pyogenic granulomas (Fig. 12-19) are small, rapidly growing, nodular, friable, vascular lesions that often bleed when touched. They occur at sites of trauma or previous surgery. Because of their vascular nature, pyogenic granulomas are best treated with curettement followed by cautery of the base. These lesions will recur if any tissue remains, and some physicians advocate complete excision. They can be confused with BCCs.

# **ACQUIRED NEVI ("MOLES")**

Acquired nevi are benign, melanocytic nevi that are absent at birth and first appear in early childhood. The lesions become more numer-

Figure 12-18 Neurofibroma.

Figure 12-19 Pyogenic granuloma.

ous until middle age, and the majority of white adults have several acquired nevi. Lesions are generally found on sun-exposed areas because the sun induces their growth.

Common acquired nevi follow a predictable developmental progression (Fig. 12-20). The earliest lesions are junctional nevi (see Fig. 12-20A), with the nevus cells at the junction between the dermis and epidermis. By late adolescence, the growths develop into compound nevi (see Fig. 12-20B), with nevus cells in both the dermis and epidermis. Compound nevi may develop hairs. By late adulthood, the lesions regress into intradermal nevi and appear nonpigmented (see Fig. 12-20C).

If the lesions lose their pigment, they may turn pink or flesh-colored. At all stages, common benign acquired nevi have smooth, distinct, symmetric borders. Patients with large numbers of acquired nevi should be monitored closely because they are at higher risk for developing melanoma.

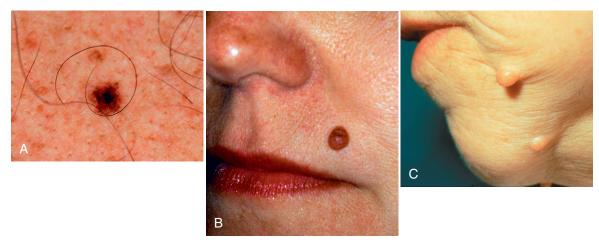

Figure 12-20 A, Junctional nevus. B, Compound nevus. C, Intradermal nevus.

Raised or pedunculated benign nevi can best be excised with a shave removal technique (optimized with the radiofrequency technique; see Chapter 30, Radiofrequency Surgery [Modern Electrosurgery]). There should be no suspicion whatsoever of melanoma if a shave technique is used. If malignancy is even a remote possibility, either a full-thickness biopsy of the lesion should be performed before removal, or the lesion should be treated by complete excision rather than shave removal. Treatment of melanomas is based solely on the depth of the lesion (see previous discussion). Superficial nevi usually do not recur, but the deeper compound nevi often do recur unless the full depth of the lesion is excised. It is difficult to determine when the entire lesion has been removed using a shave technique. The deeper dermal lesions are generally flat, whereas the superficial epidermal lesions are raised or pedunculated.

A halo nevus (Fig. 12-21) is an acquired nevus that develops a white halo around it. This is a sign that the immune system is activating against the mole, and it will soon disappear. It is the only change in a nevus that does not need a biopsy.

#### **DYSPLASTIC NEVI**

Dysplastic nevi (Fig. 12-22; a histologic diagnosis), or atypical moles (a clinical diagnosis but now also used synonymously with "dysplastic" by many pathologists), are acquired nevi that become dysplastic (precancerous) over time. The lesions are usually larger than common acquired nevi (>5 mm) and may have irregular margins, variable pigmentation, and irregular surface contours. Because the risk for melanoma is increased in patients with atypical moles and because melanoma can develop from an atypical lesion, some physicians advocate full excision of suspect lesions. Shave excisions, if done, must be deep and saucer shaped to ensure the entire depth of the lesion is removed. Once the technique of the shave excision is mastered, six to eight nevi can be shaved off in a single 15-minute

visit. Using the radiofrequency smoothing technique and moist healing minimizes scarring. Patients can have so many atypical nevi that it precludes excising all of them. These patients need to be followed closely, as do their family members. Sun protection is a must.

Should the pathologist report that the "margins are positive" in an atypical or dysplastic nevus, it behooves the surgeon to remove more tissue to ensure that the entire lesion has indeed been removed. Whether this removal is through another shave or a frank excision with suture closure depends on the exact pathology.

#### CONGENITAL NEVI

The approach to congenital nevi is based on three factors: size, color, and family history. Congenital nevi *larger than 20 cm*<sup>2</sup> often extend over large portions of the body. The lesions grow proportionally with the anatomic site, their surfaces may be irregular, and they may contain coarse hairs. Their management is very controversial because excision is difficult and deforming. The lifetime risk of these nevi developing into melanoma is 5% to 20%; therefore, some physicians advocate early removal and grafting. Others advocate close monitoring. Melanoma can develop at any site in the lesion, and biopsies of the most irregular portions of the lesions may not detect malignant change. Efforts to completely eradicate these lesions must be tempered by the potential for treatment-induced scarring and disfigurement. A 1996 study by De Raeve and colleagues suggests that vigorous curettement in the first weeks of life may be the best alternative.

Lesions between 1.5 and 20 cm<sup>2</sup> are easier to excise, and this has been generally recommended. Lesions less than 1.5 cm<sup>2</sup> are the easiest to excise but also have the lowest malignant potential. Certainly, those that are located in areas that are difficult to observe (e.g., scalp, buttocks) should be removed. Shave excisions usually are not adequate because congenital nevi are deep lesions.

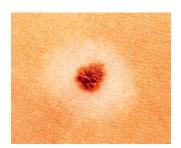

Figure 12-21 Halo nevus.

Figure 12-22 Dysplastic nevus.

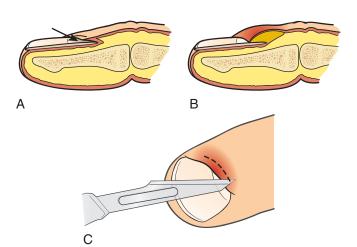

Figure 12-23 Paronychia.

Another factor to consider is the degree of pigmentation. Very light moles are less likely to degenerate into a cancer, do so later (after age 20 years), and allow early detection of changes. Dark, almost black, lesions are more likely to transform into a melanoma, do so earlier (teenage years), and are difficult to monitor, making their removal more appropriate.

The *latest recommendations suggest* observation for all congenital nevi, as with other nevi, unless changes are observed. The clinician will need to help the patient and the family sort through the various recommendations and decide on a course that is acceptable to all, including the local prevailing medical opinion.

#### **PARONYCHIA**

Paronychia (Fig. 12-23) is an infection of the distal phalanx along the proximal and lateral edges of the nail. Paronychia produces signs of local infection, including redness, tenderness, and swelling. Mild paronychia can be treated with soaks and topical antibiotics. More significant infections may develop into abscesses. As with all abscesses, it is best to incise and drain (I&D) them once a loculated area of purulence can be identified. A digital block may be needed, depending on size. The incision technique is illustrated in Figure 12-24. Occasionally packing may be used to keep the abscess from reaccumulating, but usually these abscesses are so small that it cannot be accomplished. Topical antibiotics (e.g., mupirocin [Bactroban]) may be beneficial, but unless there is marked cellulitis

**Figure 12-24** Separation of the cuticle from the nail (arrow) (**A**) can lead to a paronychia (**B**). In acute paronychia, drain any pus and consider a culture. A simple nick (**C**) through the most translucent area of the abscess is usually all that is required.

or the patient is immunocompromised, systemic antibiotics are rarely indicated. Chronic paronychia may be secondary to fungal infection.

# RASHES (EXANTHEMS, DERMATOSES)

In many cases, biopsy of a "rash" or ill-defined dermatologic lesion is not very helpful. Unless the clinical diagnosis is fairly clear, the primary care physician may be wise to obtain a dermatology consultation. Biopsies of these lesions may be indicated for clarification of a fairly discrete differential diagnosis (as with inflammatory dermatoses) or for ruling out a cutaneous neoplasm.

When multiple sites are involved, the following *simple guidelines* may be followed for selecting a lesion for a biopsy specimen: It is best to *select those areas that have the primary inflammatory changes* but are free from secondary changes such as crusting, fissuring, erosion, ulceration, and infection. Choose sites where the scars will not be obvious and where hypertrophic scarring is generally not a problem.

If the primary lesion is a *macule*, select a "fresh" lesion that is more abnormal in color. Generally, perform a punch biopsy, advancing the punch into the subcutaneous fat. *Papules* should be removed completely, if possible. Select a mature lesion without secondary changes. If the lesion is a *plaque*, the biopsy specimen should consist of the thickest area through the full depth into the subcutaneous fat. The same technique is used for *nodular* lesions and *suspected neoplastic* lesions. Alternatively, a fine-needle aspiration biopsy could be performed. For *vesicles and bullae*, *choose an intact lesion* whenever possible. Rupturing a sac makes histologic interpretation more difficult. *Sample these lesions at the margin where the blister roof is attached to the remainder of the specimen, and include normal skin*. This is virtually the only time normal skin is helpful in a biopsy to make a diagnosis (vesicular bullous disease). (See Chapter 32, Skin Bropsy.)

# SEBACEOUS HYPERPLASIA (ADENOSUM SEBACEUM)

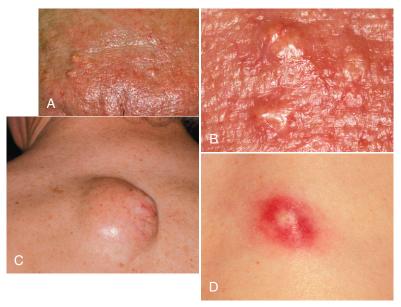

Adenosum sebaceum, or senile sebaceous gland hyperplasia, is characterized by small growths composed of enlarged sebaceous glands (Fig. 12-25A). These very small, 2- to 5-mm lesions can mimic early BCC. If numerous lesions are present in the temporal and forehead areas, they are very *unlikely* to be cancerous; BCCs are more often solitary. Treatment consists of removal of the elevated portions of the papule with shave, sharp curettement, or electrosurgical technique. Often the lesion is deep seated, and, unless curetted, it will not be entirely removed. Unlike a soft necrotic cancer, these lesions are very dense and fibrotic. Biopsy is indicated if the nature of the lesion is uncertain. However, treatment can usually be carried out on the basis of the clinical diagnosis. Cryotherapy also works well for smaller lesions.

#### **SEBACEOUS CYSTS**

The *epidermal cyst*, or *sebaceous cyst*, is a round, tense, keratinizing cyst that is freely mobile and very superficial (Fig. 12-25B and C). When located in the scalp, they are called *trichilemmal cysts* (*wens, pilar cysts*). Most patients present with a slowly growing lesion that on physical examination is subcutaneous, smooth, and nontender. A history of drainage or inflammation with purulent discharge may or may not be present, but it does help solidify the diagnosis. A small central punctum (pore) or opening helps differentiate it from a linoma.

Note the following three precautions:

 Lesions in the preauricular areas should be examined closely because parotid tumors (both adenomas and adenocarcinomas) can present as apparent "cysts." If there is any question, obtain a needle biopsy or computed tomography scan before attempting removal.

**Figure 12-25 A,** Sebaceous gland hyperplasia on the forehead of a 52-year-old male. Usually lesions are multiple and popular. **B,** When larger, or on close inspection, sebaceous gland hyperplasia can resemble basal cell carcinoma (BCC). However, BCCs are rarely multiple like this. **C,** Sebaceous cyst. **D,** Inflamed sebaceous cyst.

- 2. "Cysts," especially in infants (but also in children) have a higher likelihood of being dermoids (also known as fusion plane cysts), which may have fistulous connections with deeper spaces. Fortunately, cysts in the most common location of the lateral third of the eyebrow can be easily removed. But all others, including on the nasal bridge, the scalp, the neck, and the postauricular areas, may have intracranial connections. Consider magnetic resonance imaging first to exclude a contiguous tract. If present, removal will require a neurosurgical consult. Seventy percent of dermoid cysts will appear by 5 years of age and are more worrisome if they contain hair or capillary changes.
- 3. "Everything is what it is until it ain't!" The majority of sebaceous cysts are easy to differentiate. However, they have been misdiagnosed, with the underlying pathologic process being metastatic melanoma or other cancer. The only way to be sure of the diagnosis is to remove them.

Many believe asymptomatic lesions can be watched. The down side to this strategy is that they can grow, making removal more difficult. Or, they can become infected. If the patient asks for removal because of irritative symptoms or growth, the lesion should be removed. Once the characteristic sebaceous material and smell are observed, they *do not* need to be sent to pathology.

In the past, a surgeon's adeptness was often judged by whether he or she could remove the lesion intact without rupturing the capsule. This requires sterile technique and a fairly generous incision over the area with judicious removal of the *entire* sac, to decrease the likelihood of any recurrence. The cavity is then irrigated and closed with sutures.

Another, simpler technique is preferred by patient and physician alike where the skin is thinner (e.g., face); it does not work well with thick skin (e.g., back). Maintaining an intact sac during removal is no longer thought to be required. After anesthesia, a small, 5- to 6-mm incision is made directly into the cyst using a no. 11 blade. Some prefer to use a 3- or 4-mm sharp dermal punch. All contents are expressed using external pressure. Frequently (especially in scalp cysts, where the sac is thick and firm), this external pressure will not only extrude the sebaceous material of the cyst but the sac itself (Fig. 12-26). (Do not use the punch method on the scalp because of the thickness of the sac.) If the sac is not produced, then curved hemostats are inserted into the wound and repeated

attempts are made to grasp the sac and gently tug it out in its entirety. A 3- to 4-mm dermal curette can also be inserted into the cavity to curette away any possible residual sac. No suture closure is indicated, so sterile technique (e.g., draping) is not indicated. If blood accumulates or the wound gets infected (both very rare), the patient just expresses it. Should some of the sac be left behind and the cyst reform, then formal excision with suture closure will be required.

This simple method of cyst treatment is usually successful unless the cyst is quite large (>2 cm), it has been infected previously, a previous attempt at removal has been made (causing surrounding scarring), or it is deep in the skin tissue. Wens, large and small (0.5–4 cm), are almost always treated successfully with the minimal incision technique, even with prior infection. The sacs are much thicker—almost like ping-pong balls! Three to four wens can readily be removed in a 15-minute visit (Fig. 12-27). Up to 95% of all sebaceous cysts can be treated with this simple method, without recurrence.

A variation on the technique just described is to insert two large iodine crystals (iodine crystals USP) into the sac after expression of the contents. The sac for some reason contracts around the crystals in 48 to 72 hours; the clinician then easily expresses the entire complex through the incision. This technique can also be used if it appears that the entire sac has not been removed using the simple technique described previously.

For those cysts in which the aforementioned method is not recommended (as noted), excision is necessary. Perform a field block with local anesthesia. Using a scalpel, make a small fusiform incision in the direction of the skin lines over the top of the cyst that includes the punctum. The length should be just less than the size of the cyst. Be careful to incise lightly because the skin is often very thin. Dissect deeply first into the adipose tissue at the two ends of the incision, being careful not to rupture the sac. A curved Metzenbaum scissors works well. Use an Allis clamp to grasp the wedge of skin (still attached) over the cyst. Apply only light pressure because the skin separates easily. This traction, however, will lift up the cyst below. Continue dissection until the cyst is free. Should the cyst rupture, one can proceed with the dissection, or express the entire contents, then continue to dissect the sac out. Be sure to remove the entire sac or the cyst is more likely to recur. Irrigate the cavity with saline and then close, usually with an intermediate closure technique.

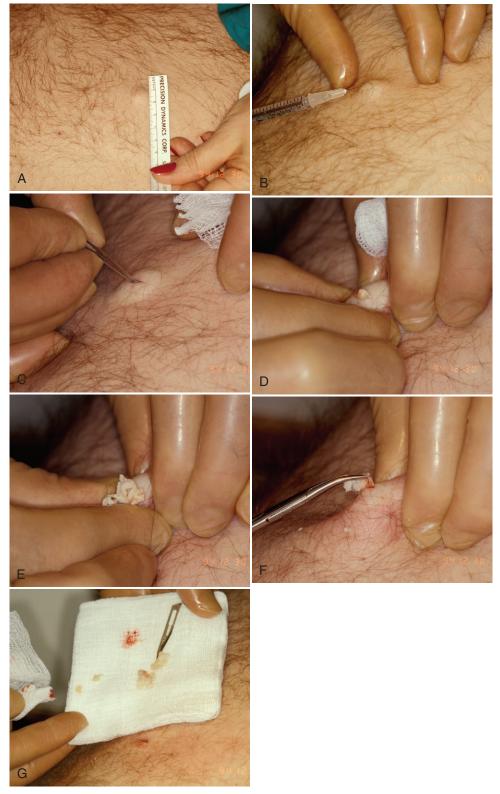

Figure 12-26 A, Sebaceous cyst (1.5 to 2 cm). B, Inject I mL of local anesthetic over the top of the cyst to form a wheal. C, Incise with a no. II blade directly into the cyst. D, Express the contents of the cyst. E, Sebaceous material. F, Grasp the sac with hemostats and tease it free with gentle pressure and a rocking motion. G, Sebaceous material and appearance of wound after removal. No closure is needed for a small incision. (Courtesy of The Medical Procedures Center, P.C., Midland, Mich.)

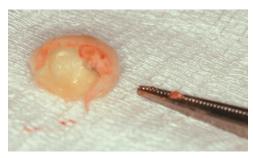

Figure 12-27 Typical sac from a trichilemmal (pilar) cyst, or wen.

If infected, sebaceous cysts pose a bigger problem. The treatment for an abscess is to I&D it! Antibiotics are costly and often there is not really an infection; rather, the cyst has ruptured, causing an inflammatory response. Treatment is the same: I&D. Formal excision is ill advised because infection is likely to occur if sutures are placed.

## **Technique**

See Chapter 20, Incision and Drainage of an Abscess.

- 1. Prep with alcohol. Inject 2 mL of 2% lidocaine with epinephrine over the top of the lesion.
- Use a no. 11 blade to incise the lesion. Be careful because the contents are often under pressure and come "flying out." All sebaceous material must be removed.
- Insert hemostats to break up any pockets. Try to remove the sac as noted previously, but it is usually too friable. Use a reusable dermal curette and curette the inside, which may remove the sac.
- 4. Place ¼-inch iodoform gauze into the wound. Leave a small tail on the outside.
- 5. Cover with ointment so the dressing does not stick. Change the dressings two to three times per day. Change the gauze in 1 week and replace with clean gauze. Remove the new gauze in 3 weeks and let the wound heal.

Usually the cyst will not recur but rather scar down. If it recurs, formal excision is necessary, but not until the infection has resolved. No antibiotics are necessary after an I&D.

#### **T**ELANGIECTASES

Small *cherry hemangiomas*, a type of telangiectasia, are benign, small, red vascular lesions that do not require treatment. If irritated or bleeding, they can be lightly cauterized and wiped off with a gauze. (See earlier discussion.) Malignancy is not a consideration. *Spider veins*, another type of telangiectasia, are best treated with sclerotherapy if on the legs. Radiosurgery with a 30-gauge needle works extremely well on the face for isolated lesions, but works poorly in the lower extremities (see Chapter 30, Radiofrequency Surgery [Modern Electrosurgery]). Spider veins in the leg can produce significant pain and paresthesias if left untreated (see Chapter 92, Sclerotherapy). When the veins are very fine and dense such as with rosacea, IPL works extremely well.

## WARTS (VERRUCA VULGARIS AND PLANTARIS)

The recurrence rates associated with all treatments of common warts are 30% or higher. Most over-the-counter and prescription preparations are acidic, caustic solutions. In time, 60% of warts resolve spontaneously. Vitamins enhance the immune system and may aid wart resolution. Numerous treatment methods are used and noted in Table 12-1 (see Chapter 42, Wart [Verruca] Treatment). Candida antigen injections are efficacious, cost effective, and the least traumatic of the alternatives, with virtually no residual scarring.

Plantar warts are treated with methods similar to those used with common warts. Physicians should avoid surgical excisions on the bottom of the feet because the scar tissue often remains painful after healing. A patient may suffer with the irritated scar, which produces an effect not unlike a pebble in a shoe. Soaking followed by paring of callous tissue will improve the efficacy of any treatment. Cryotherapy is effective and does not result in scarring. Treatment with Candida antigen has become the first-line approach in all but the simplest cases of verruca.

## WARTS (CONDYLOMA ACUMINATA)

See Chapter 155, Treatment of Noncervical Condylomata Acuminata.

#### **WENS**

See the previous section on sebaceous cysts.

#### **X**ANTHELASMA

Xanthelasma, the most common form of xanthoma, is a yellow-white plaque on the eyelids. The diagnosis of xanthelasma can be made clinically. The goal of all treatments is to stay very superficial. Light fulguration or cauterization is often sufficient. With radiofrequency loop ablation, it is easier to control depth. Use the large loop at pure cutting level 2 (20 watts) and lightly vaporize the lesions until no residual white material exists. Often, if small, an incision can be made with an 18-gauge needle and the lesion can be expressed. Surgically removing the abnormal tissue with a curvilinear elliptical excision provides excellent results when repaired using a 6-0 suture. Because of the nature of the lesion, recurrences are common.

## **CPT/BILLING CODES**

10060 I&D cyst/abscess, simple

10061 I&D cyst/abscess, complex or multiple

11200 Skin tag removal by excision or destruction: 1-15

11201 Each additional 10 or portion thereof

**NOTE:** If the sac is removed or gauze is placed, this is considered "complex."

Coding and billing of lesion removal and destruction are very complex. There are excision codes with simple and intermediate closures. Shave excisions are another whole section in the CPT code book. Destruction of lesions depends on whether they are benign or malignant, their size, and where they are located. For genital and anal lesions, it also depends on how they are "destroyed." It is of the utmost importance that the clinician differentiates the methods for the treatment of these lesions when coding and billing. Clinicians should consider obtaining the current year's edition of The NPI Reimbursement Manual for Office Procedures (Pfenninger JL, editor, The National Procedures Institute, www.npinstitute.com). This manual not only lists appropriate procedure codes but provides a comparison and suggested fee for each procedure code commonly used for all procedures by primary care clinicians, not just dermatologists. A videotape/DVD discussing coding and billing is also available from the same source.

## **ADDITIONAL RESOURCES**

Multiple patient education forms for different diagnoses and conditions are available at www.expertconsult.com.

Multiple videotapes/DVDs are available from the National Procedures Institute depicting treatment techniques for the methods and approaches discussed in this chapter. www.npinstitute.com (phone 1-866-NPI-CME1).

# **BURN TREATMENT**

Roberta E. Gebhard

One million people seek medical advice for burns each year in the United States. Burn injuries can cause both severe psychological and physical disability. Early resuscitation and aggressive surgical intervention of burn injuries can reduce mortality and limit long-term morbidity.

## BURN COMPLICATIONS REQUIRING RESUSCITATION

Inherent to burn injuries are a number of potential complications. Burn research has shown that the causes of early mortality are not the burns themselves, but complications related to hypoxia, hypoventilation, and circulation disorders, including hypovolemia and hypothermia. Complications requiring early resuscitation are as follows:

- Airway injury (airway edema from thermal or chemical burns)
- Inhalation injury/hypoxia
  - Chemical fumes are the most common cause of pneumonitis/ pulmonary edema.
  - Smoke or other particulate material causes pneumonitis.
  - Carbon monoxide poisoning is common with fires in enclosed spaces.
- Hypothermia from loss of skin integrity and evaporative losses
- Hypovolemia or shock resulting from intravascular-to-extravascular fluid shifts and pain-vasoconstriction
- Cardiac asystole and arrhythmias (especially with high-voltage burns)

## RESUSCITATION FOR EARLY BURN COMPLICATIONS

Advanced Burn Life Support (ABLS) courses are available both in traditional and online formats that help focus resuscitation efforts to the most critical patient needs by using a simple-to-remember alphabetic mnemonic: A = Airway, B = Breathing, C = Circulation, D = Disability, E = Exposure, F = Fluids (see the "Online Resources" section at the end of the chapter).

## A = Airway

Airway management is the crucial first step in resuscitating a severe burn victim. Early endotracheal intubation is recommended when an injured airway is first diagnosed. Although airway edema normally stays above the vocal cords, delayed intubation can be much more difficult or traumatic. The manifestations of airway injury are often subtle and may not appear for 24 hours. A history of the victim being confined in a burning building (or closed space) or of having impaired mentation is suggestive of acute inhalational injury. With this history, a search for clinical evidence of inhalation injury should be undertaken carefully. Clinical clues to acute inhalation injury

include facial burns, singed eyebrow or nasal hairs, oropharyngeal carbon deposits, acute inflammation, and carbonaceous sputum. If hoarseness, a brassy cough, or stridor develops, immediately intubate the patient. Intubation is also required before transport if transportation time will be prolonged. Airway injuries indicate major burn severity.

## **B** = **Breathing**

Evaluate the patient for spontaneous respirations. Check for stridor, wheezing, or rales and administer 100% O<sub>2</sub> as soon as it is available. Carbon monoxide (CO) poisoning should be assumed if the burn victim was trapped in an enclosed space.

#### C = Circulation

Rapid shifts in intravascular fluid occur in burns of greater than 20% to 25% total body surface area (TBSA). Hypovolemia resulting from capillary leak and evaporative losses should be anticipated and corrected (see "F = Fluids" section). High-voltage burns can cause cardiac arrest. Lower-voltage injuries may cause delayed arrhythmias. After removing the electrical source with a nonconducting piece of equipment or turning off the power source, begin basic life support in the pulseless victim. Advanced cardiac life support measures should be initiated as soon as appropriate equipment is available.

#### D = Disability

Remember to stabilize the cervical spine to prevent further disability. High-voltage injuries can cause tetanic muscle contractions severe enough to fracture the cervical spine, lumbar spine, or limbs. Jumps from burning buildings can also cause fractures.

## E = Exposure

- Expose the patient by removing any nonadherent clothing, especially chemically contaminated or smoldering clothing, constricting clothing, and jewelry.
- Examine for associated injuries. Document these injuries and address them after the patient is stabilized.
- Brush away residual dry chemicals. Irrigate liquid residual chemicals copiously with water. Alkalis may require forceful irrigation (such as a shower) for up to an hour.
- Cover the patient with a clean, dry blanket to prevent hypothermia.

#### F = Fluids

Aggressive fluid resuscitation is required in patients with burns covering more than 25% TBSA to prevent hypovolemia and shock resulting from capillary leak and evaporative losses.

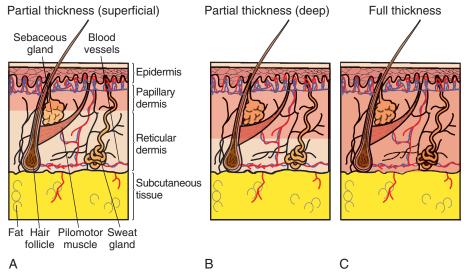

Figure 13-1 A, Superficial partial-thickness burn. B, Deep partial-thickness burn. C, Full-thickness burn. Coral background area denotes depth of burn injuries. (Reproduced from Edlich RF, Bailey TL, Bill TJ: Thermal burns. In Marx JA, Walls R, Hockberger R [eds]: Rosen's Emergency Medicine: Concepts and Clinical Practice, 5th ed. Philadelphia, Mosby, 2002, pp 802–813.)

#### Intravenous Access

Insert two large-bore intravenous (IV) lines, avoiding burned skin if possible. Central venous access may be needed.

#### Parkland Formula

The most widely used formula for fluid resuscitation is the Parkland Formula, although there is some controversy that it may underestimate the initial need for fluid (see Holm and colleagues, 2004). The greatest intravascular-to-extravascular fluid shifts occur in the first 8 hours. Significant but slower fluid shifts continue for the next 16 hours. All fluid resuscitation formulas are designed to replace the intravascular volume as it is lost, most rapidly in the first 8 hours, then the next 16 hours.

- First 24 hours: lactated Ringer's 4 mL/kg/percent burn (first half given in first 8 hours, second half given in next 16 hours). Time is measured from the onset time of burn.
- Second 24 hours: colloid 0.5 mL/kg/percent burn + 2000 mL of 5% dextrose in water (given over second 24 hours).
- Example: 70-kg adult with 50% TBSA partial- and full-thickness burns requires 14 L of lactated Ringer's over the first 24 hours (4 mL × 70 kg × 50% burn = 14,000 mL/24 hr). Seven liters is given in the first 8 hours (875 mL/hr) and 7 L given in the next 16 hours (437.5 mL/hr).
- Evaluation of fluid resuscitation efforts is best gauged by urine output (see "Inpatient Management for the Primary Provider" section).

## **ESTIMATING BURN SEVERITY**

Burn depth, size, and locations on the body must be assessed to determine the burn severity.

## **Burn Depth**

Figure 13-1 shows the skin in cross-section with the layers involved with superficial partial-thickness, deep partial-thickness, and full-thickness burns.

Superficial burns are erythematous without blister formation and involve only the epidermis; pain is localized (Fig. 13-2). Superficial partial-thickness burns are painful, warm, and moist with blister formation; they involve the epidermis and superficial papillary dermis

(Fig. 13-3). With *deep partial-thickness* burns the skin is mottled, waxy, and white in appearance, with ruptured blisters. Pain sensation is absent, but pressure sensation is intact (Fig. 13-4). *Full-thickness* burns involve both the epidermis and dermis, have a white to gray, leathery appearance, and do not blanch with pressure. There is only sensation to deep pressure; there is no pain because pain receptors in the dermis are destroyed (Fig. 13-5).

Burn depth terminology no longer includes the use of "first-, second-, and third-degree burns." Note that superficial and superficial partial-thickness burns have minimal to no risk of scarring, are painful, and heal spontaneously by 3 weeks. Deep partial-thickness and full-thickness burns have a higher risk of scarring, decreased sensation, and delayed healing of greater than 3 weeks. Fourth-degree burn is the term still used to depict the most severe burns, extending through both the epidermis and the dermis and into the fascia and muscle. Fourth-degree burns are life-threatening and may never heal if they are present over more than 2% of TBSA (see later).

Figure 13-2 Superficial burns are erythematous without blister formation, involve only the epidermis, and are characterized by localized pain.

**Figure 13-3** Superficial partial-thickness burns are painful, warm, and moist with blister formation, and involve the epidermis and superficial papillary dermis.

Initial estimates of the depth of the burn are crucial to timely triage. The final depth of injury cannot always be predicted at the initial evaluation; therefore, sequential evaluations may be needed to revise the depth of the burn over the days and weeks after the injury. See Figure 13-6 for treatment recommendations based on wound depth assessment.

## Burn Size: Percentage of Total Body Surface Area

Burn size is an important determinant of burn healing. Healing occurs from fibroblasts migrating in from the burn margins and the oil glands and hair follicles (skin appendages). The skin appendages penetrate deep into the dermis and, except for full-thickness burns, are spared from destruction.

The adult body surface area can be divided into percentages of nine and multiples or fractions of nine: the "Rule of Nines" (Fig. 13-7). Infants have a greater proportion of TBSA on the head and neck and less on the legs. The posterior torso, including buttocks, still equals 18%, with each buttock equaling 2.5%. Palms are 1.25%.

## **Burn Locations**

The determination of whether a particular burn injury should be treated as an ambulatory case, a local hospital admission, or a direct admission to a regional burn center depends on burn involvement in some highly critical areas.

The American Burn Association (ABA) has set up criteria for referral to a burn center for treatment (Box 13-1). The ABA's grading system recommends disposition to a burn center for these critical conditions because of the significantly increased risk of morbidity.

**Figure 13-4** With deep partial-thickness burns the skin is mottled, waxy, and white in appearance, with ruptured blisters.

**Figure 13-5** Full-thickness burns involve both the epidermis and dermis, have a white to gray, leathery appearance, and do not blanch with pressure.

Certain burn locations or other potential injuries lead to automatic classification as *moderate burn severity*. Fractures in association with burns increase the severity index.

## Disposition of Patient Based on Burn Severity: American Burn Association Guidelines

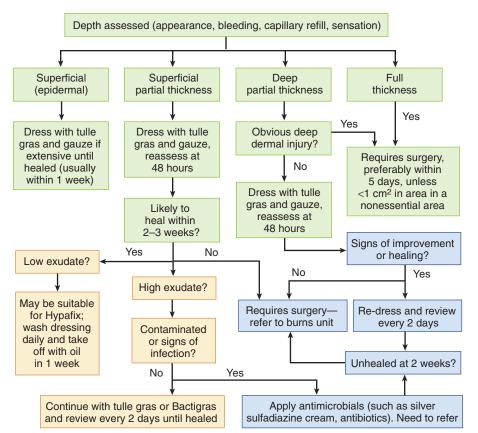

The ABA guidelines for disposition of burn patients are based on burn severity, which is based on depth, size, and location of the burn (see Box 13-1).

- Minor burns: outpatient management
  - Involve less than 10% TBSA in adults, less than 5% TBSA in children and elderly
  - Less than 2% TBSA full-thickness burns
  - Do not involve face, hands, feet, genitalia, or respiratory tract
  - Are not circumferential
  - No associated injuries or comorbidities
- Moderate burns: hospitalization
- Major burns: burn center

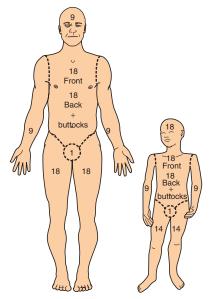

## COMPLICATIONS ENCOUNTERED DURING BURN MANAGEMENT

Additional complications are encountered during the treatment of burns, whether in the hospital or as an outpatient. Any life-threatening complications encountered during the resuscitation phase of burn care require continued attention after the patient is stabilized and disposition has been determined. Burn centers offer expertise in wound management and vigilance in late complications. Other complications that must be prevented if possible and addressed if they occur despite all preventive efforts include the following:

- Airway injury
  - Hypoxia
  - Airway edema
  - CO poisoning: PO<sub>2</sub> levels on blood gases may be normal even in the presence of CO poisoning. Carboxyhemoglobin (CO-Hgb) levels should be measured. The presence of 100% O<sub>2</sub> provides appropriate supplementation and reduces CO levels. (The T<sub>1/2</sub> of CO-Hgb converting back to hemoglobin is reduced from 250 minutes on room air to 40 minutes on 100% O<sub>2</sub>.) Severe cases of CO poisoning should receive hyperbaric oxygen therapy, which can be life-saving. See Figure 13-8 for an algorithm on using the hyperbaric chamber for CO poisoning.
  - CO poisoning symptoms are related to the percentage of CO-Hgb: CO-Hgb levels less than 20% are usually asymptomatic. At CO-Hgb levels of 20% to 30%, headache and nausea

**Figure 13-6** Algorithm for assessing depth of burn wounds and suggested treatment.

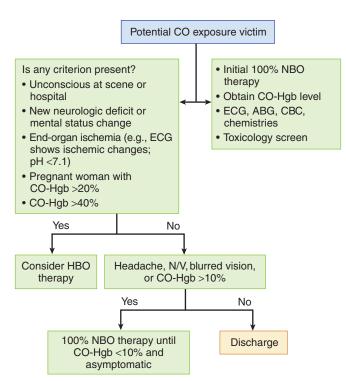

**Figure 13-7 Rule of nines.** (Modified from Krisanda TJ, Bethel CA: Burn care procedures. In Roberts JR, Hedges JR [eds]: Clinical Procedures in Emergency Medicine, 3rd ed. Philadelphia, WB Saunders, 1998.)

## Box 13-1. Burn Center Referral Criteria

A burn center may treat adults, children, or both. Burn injuries that should be referred to a burn center include the following:

- Partial-thickness burns of greater than 10% of the total body surface area.
- Burns that involve the face, hands, feet, genitalia, perineum, or major joints.
- Third-degree burns in any age group.
- Electrical burns, including lightning injury.
- Chemical burns.
- Inhalation injury.
- Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality.
- Any patients with burns and concomitant trauma (such as fractures) in which the burn injury poses the greatest risk of morbidity or mortality. In such cases, if the trauma poses the greater immediate risk, the patient's condition may be stabilized initially in a trauma center before transfer to a burn center. Physician judgment will be necessary in such situations and should be in concert with the regional medical control plan and triage protocols.
- Burned children in hospitals without qualified personnel or equipment for the care of children.
- Burn injury in patients who will require special social, emotional, or rehabilitative intervention.

Excerpted from Committee on Trauma, American College of Surgeons: Guidelines for the operation of burn centers. In Resources for Optimal Care of the Injured Patient 2006. Rockford, Ill, American College of Surgeons, 2006, pp 79–86.

**Figure 13-8** Algorithm for using normobaric oxygen (NBO) and hyperbaric oxygen (HBO) after carbon monoxide exposure. ABG, arterial blood gas; CBC, complete blood count; CO-Hgb, carboxyhemoglobin; ECG, electrocardiogram; N/V, nausea/vomiting. (Adapted from O'Brien C, Manaker S: Carbon monoxide and smoke inhalation. In Lanken PN, Hanson CW III, Manaker S [eds]: The Intensive Care Unit Manual. Philadelphia, WB Saunders, 2001.)

occur. At CO-Hgb levels of 30% to 40%, confusion occurs, and coma ensues when CO-Hgb levels reach between 40% and 60%. Levels over 60% cause death.

- Cardiac arrhythmias: Can occur for up to 3 days after highvoltage injury
- Pain
- Infection
  - Bacterial
  - Tetanus
  - Smoke inhalation/pneumonitis
  - Pneumonia
- Hypothermia
- Intravascular-to-extravascular fluid shifts
  - Hypovolemia/shock
  - Edema
- Compartment syndrome
- Hypertrophic scars/contractures
  - Loss of function of hands, feet, eyes, joints, genitalia
  - Permanent disfigurement (Fig. 13-9)

Figure 13-9 Permanent disfigurement.

- Pigmentary changes
  - Hypopigmentation for 6 to 24 months
  - Hyperpigmentation if not protected from ultraviolet damage
- Sensory dysfunction (sensory nerve damage)
  - Hyperesthesias
  - Pruritus
- Xerosis (damaged sweat glands)
- Psychological
  - Depression
  - Anxiety disorders
- Carcinoma (nonmelanoma skin cancers) in burn scars

## INPATIENT MANAGEMENT FOR THE PRIMARY PROVIDER

According to the ABA's grading system for burn severity and disposition of patients, moderate and major burn injuries require hospitalization either locally or in a burn center. The primary provider may be the admitting provider for moderate and even severe burns if stabilization is needed before transfer to a burn center. The ABA's website (www.ameriburn.org) has search capability to assist in locating burn centers throughout the United States. Inpatient management of patients with moderate burn severity should include consideration of the following:

- History of burn injury
  - When? Initial time of burn important for fluid resuscitation.
  - How? Fire, steam, chemical, electrical, hot material?
- Where? Enclosed space (inhalation injury)?
- Medical history
  - Medical problems: diabetes and chronic steroid use increase risk of infection. Cardiopulmonary disease decreases physical reserves. Other medical problems will need to be addressed.
  - Medications: steroid use, blood thinners, diabetic medications, and so forth.
  - Allergies: sulfa allergy (use bacitracin ointment).
  - Last tetanus: boost if not received in last 12 months.
- Airway: suspected airway injury may need intubation if oropharyngeal edema develops during the 12 to 24 hours after injury.
   Observe for raspy cough, hoarseness, or stridor.
- Breathing: monitor for hypoxia.
  - CO poisoning:  $100\% \stackrel{\bullet}{O}_2$  or hyperbaric oxygen therapy (see Fig. 13-8).
  - Pneumonitis or pulmonary edema: ventilation with high O<sub>2</sub> and positive end-expiratory pressure may be needed.
  - Pneumonia: treat with appropriate systemic antibiotics.
- Circulation
  - Monitor urine output for adequate rehydration.
  - Monitor for cardiac arrhythmias with telemetry. Patients with high-voltage (>440 V) injuries can develop ventricular arrhythmias up to 3 days after the injury. The most common electrocardiographic (ECG) finding of cardiac injury after electrical burn is nonspecific ST segment—T-wave abnormalities. These patients should be admitted to the telemetry unit for cardiac monitoring until the ECG normalizes. Treat with appropriate antiarrhythmics.
  - Monitor for compartment syndrome for circumferential wounds or if excessive rehydration.
    - Clinical diagnostic signs: delayed capillary refill, distal anesthesia, increasing limb pain, and decreased or absent distal pulses. Clinical signs are only 60% sensitive (they miss 40% of true compartment syndromes).
    - Measure direct compartment pressures (see Chapter 188, Compartment Syndrome Evaluation).
    - Obtain surgical consultation for escharotomy of affected limb, including across joints. Rarely needed for circumferential burns of trunk.

Fasciotomy will be necessary if escharotomy is not effective.

- Disability: obtain an x-ray skeletal survey for high-voltage burn or other suspected bone injury. Tetanic convulsion can cause fracture of cervical spine, lumbar spine, or limbs. A cross-table lateral view of the cervical spine should be obtained before removal of full cervical spine precautions. Monitor the level of consciousness; mental alertness confirms adequate circulation.
- Exposure: Avoid hypothermia, which can increase peripheral vasoconstriction. Evaporative fluid loss and loss of barrier to infection result from partial- and full-thickness burns. Consider early excision of eschar and skin grafting or artificial covering.
- Fluids: Continue rehydration per urine output. For adults, adequate urine output is 0.5 mL/kg/hr; for children, 1.0 mL/kg/hr is needed. A Foley catheter is required. Excessive fluid administration can lead to increased edema, increased rate of compartment syndrome, and unnecessary fasciotomies. Higher urine output and osmotic diuretics are normally required for high-voltage burns to prevent acute renal failure from rhabdomyolysis.
- Requirements decrease as the capillary leakage decreases over 2 to 7 days.
  - Admission weight and daily patient weights are required. Increased insensible losses through open wounds make patient weight invaluable.
  - Inputs and outputs: hourly fluid input and output are required to monitor the massive amounts of fluid used for resuscitation.
- Give tetanus prophylaxis for burns deeper than superficial partial thickness (if time since last tetanus booster is >12 months).
- Early nutrition first 12 to 24 hours, enteral if possible: Burn injuries are associated with an increased metabolism from 1.3× to 2× baseline. Enteral feedings decrease gastrointestinal ulceration. Parenteral feedings may be required but significantly increase the risk of sepsis at IV sites. Catheters should be replaced every 48 to 72 hours.
- Infection: Common sources of infection in burn patients include the burn wounds, pneumonia, IV line sepsis, and urinary tract sepsis from indwelling catheters. Burn wound infections usually require full-thickness biopsy and tissue culture to differentiate bacterial colonization from bacterial tissue invasion. Systemic antibiotics are required. Excision of infected burn tissue and grafting are often required. Culturing of central line catheter tips on replacement is recommended. Worsening pulmonary status should prompt a chest radiographic examination.
- Pain: Baseline pain medication with augmentation of pain relief by rescue medications is recommended. Some authorities recommend treatment of baseline pain with methadone and augmentation with morphine before dressing changes or activities such as physical therapy.

## **WOUND CARE**

## **Burn Débridement**

- Devitalized tissue removal is important to prevent bacterial colonization. Mild soaps such as chlorhexidine are recommended.
   Avoid povidone—iodine (Betadine), alcohol, and hydrogen peroxide, which inhibit fibroblasts as well as bacteria, delaying the healing process.
- Remove ruptured blisters, those blisters prone to break (e.g., over joints), and those with cloudy fluid that could be infected.
- Removal of small intact blisters is controversial. Some authorities recommend débridement of all blisters, whereas others recommend leaving them undisturbed as a natural sterile barrier to infection.

**NOTE:** Delayed blister resolution longer than 2 weeks may indicate deep partial-thickness burn. Consider consultation for excision and skin grafting.

 Removal of adherent tar or clothing can be facilitated by application of petroleum jelly or bacitracin ointment for softening and removal during washing at dressing changes. Whirlpool baths are well tolerated for wound débridement.

## **Dressings**

- Standard dressings are changed twice a day. After dressing removal, the wounds are washed, inspected for healing or onset of infection, patted dry, treated with topical antibiotics, and covered with Telfa (Smith & Nephew, London), a nonadherent dressing, and gauze or stockinet. Tulle gras dressings are gauze impregnated with paraffin, and Bactigras (Smith & Nephew) is a tulle gras with 0.5% chlorhexidine acetate. Both can be used as an alternative to Telfa. Hypafix (Smith & Nephew) is an adhesive retention tape that is air and moisture permeable and completely covers the entire dressing to reduce contamination.
- Consider Unna paste dressings. Advocates cite benefits such as decreased scarring, discomfort, and cost without increased infection rate. Dressings are changed every 3 to 7 days. Concerns include delayed detection of infection and overlooking of early scarring or other complications because of infrequent wound observation.

## **Topical Antibiotics**

Topical antibiotics are used to decrease bacterial colonization of open blisters and deep burns. Their use significantly decreases wound infections. No single agents can be used in all cases. Several choices include the following:

- Silver sulfadiazine (Silvadene 1% cream). Silver sulfadiazine has intermediate eschar penetration and a broad spectrum of antibacterial and anticandidal activity. It is easy to apply but should not be used on the face because of staining or in patients with sulfa allergy or glucose-6-phosphate dehydrogenase (G6PD) deficiency. Silver sulfadiazine should not be used in pregnant women, newborns, and breast-feeding women of children 2 months of age or younger owing to risk of sulfonamide kernicterus if it is absorbed through the skin.
- Mafenide acetate (Sulfamylon 8.5% cream). Mafenide acetate has
  excellent eschar penetration and has the best antibacterial spectrum. It should be used on ears for prevention of chondritis. Some
  authorities recommend it on all full-thickness burns. Mafenide is
  painful after it is applied and expensive. Sleep disturbance is fairly
  common after evening application. It is a carbonic anhydrase
  inhibitor; metabolic alkalosis may occur.
- Bacitracin zinc ointment 1%. Bacitracin is best used for facial burns, around mucous membranes, in patients with sulfa allergy, and for loosening adherent tar or clothing before removal. Advocates note that it is inexpensive, readily available without prescription, and often effective. Bacitracin does not have good eschar penetration, has a narrower spectrum of antibacterial action, and can cause topical sensitization. It has no activity against Candida albicans. Controlled trials are needed comparing bacitracin with silver sulfadiazine.
- Combination. Some authorities recommend Sulfamylon for morning dressing change and Silvadene for the evening dressing change. The latter is considered painless with less sleep disturbance.
- Alternatives to topical antibiotics. Biologic dressings such as pigskin
  or allografts; biosynthetic dressings such as Integra, Alloderm
  (LifeCell Corporation, Branchburg, NJ), Epicel (Genzyme,
  Cambridge, Mass), TransCyte and Biobrane (Smith & Nephew);
  and Xeroform (Smith & Nephew), a bismuth-impregnated petroleum gauze, produce faster healing and lower infection rates, but
  need to be placed within 6 hours of injury. Their use is limited
  by lack of availability at the point of entry to the health care
  system, high cost, and difficulty of use.

## **Excision and Skin Grafting**

- Benefits of excision of the eschar and skin grafting include prevention of hypertrophic scarring and contractures as well as protection of deep tissues such as muscles and tendons (see Chapter 33, Skin Grafting). Decreases in evaporative fluid loss, pain, and susceptibility to infection are noted. Reduced time for rehabilitation and reduced time in hospital are also significant.
- A negative aspect of early excision and grafting is significant blood loss in a critically ill patient. Decreased blood loss occurs if excision is performed one day and grafting the following day.
- Options for skin grafting with the patient's own skin (autograft) include full-thickness versus split-thickness grafts as well as sheet grafts versus mesh grafts.
- Other grafting materials include allografts (cadaver), xenografts (usually porcine), cultured skin cells, and dermal substitutes such as collagen and bilayer substitutes (both dermal and epidermal components). See also the previous discussion of alternatives to topical antibiotics.

## Prevention of Contractures and Hypertrophic Scarring

- Early consultation with a burn specialist or surgeon with burn experience is recommended. Hypertrophic scarring and contractures are best prevented and, once started, are more difficult to treat.
- Hypertrophic scarring can occur up to 2 years after the burn injury.
- There is an increased risk of contracture in deep partial-thickness burns and full-thickness burns, black patients, and at extremes of age range, both young and old.
- Late excision (after 2 weeks) of eschar and skin grafting for deep partial-thickness or full-thickness burns masked by blisters should be done. Nonresorption of blister by 2 weeks is a diagnostic clue.
- Early involvement with physical therapy and occupational therapy decreases contractures. Active range of motion (ROM) and stretching are superior to passive ROM in decreasing the risk of contracture. Avoid splinting of extremity burns if at all possible.
- Pressure dressings decrease hypertrophic scarring, even if initiated as late as 12 months after the burn injury, but early pressure dressing use is superior.
- Silicone sheeting like ReJuveness or Scar Fx (Scar Heal) can reduce hypertrophic scarring if used up to 12 years after the injury.

## AMBULATORY MANAGEMENT FOR THE PRIMARY PROVIDER

Management of the majority of the 1 million burns per year in the United States occurs in an ambulatory setting. The primary provider is well equipped to manage the initial and follow-up burn care for minor burns. Minor burns involve less than 10% TBSA of adults, less than 5% TBSA of young and old patients, and less than 2% TBSA full-thickness burn; they do not involve the face, hands, feet, genitalia, or respiratory tract. They are not circumferential. These patients do not have significant associated injuries or comorbidities that predispose to infection.

### **Initial Ambulatory Visit**

- Evaluation of burn severity and inclusion of only minor burns.
- Tetanus prophylaxis, if indicated.
- Burn débridement. (Give field block or regional anesthesia for discomfort; remove devitalized tissue, ruptured blisters, and blisters likely to rupture.\*)
- \*The "Inpatient Management for Primary Provider" section of this chapter includes more extensive discussion of this topic.

- Wound washed with mild soap and warm water. (This is a clean but not sterile procedure.\*) Skin disinfectants are no longer recommended because they are thought to delay wound healing.
- Wound dressing changes twice a day.\*
- Early referral for excision of eschar and skin grafting as outpatient, if indicated.<sup>†</sup>
- Pain control: nonsteroidal anti-inflammatory drugs or acetaminophen recommended for baseline pain. (Prescribe oral narcotic pain relievers [e.g., acetaminophen with codeine] for beforedressing changes, for breakthrough pain, and at bedtime for pain during sleep.)
- Avoidance of splinting and encouragement of active ROM and stretching.
- Full-thickness burns less than 3 cm in diameter in a nonfunctional, noncosmetic area with normal-thickness skin may be allowed to heal by contracture.
- Patient teaching guide (see the patient education form available online at www.expertconsult.com).
- Follow-up appointment scheduled for the day after the burn injury.

## **Second Ambulatory Visit**

- During the dressing change, reevaluation of burn severity (location, size, and depth), evaluation of pain control, and possible further wound débridement.
- Teaching wound care and dressing changes at this visit.
- Teaching patient to observe for infection, scarring, or other complication.
- Patient referral to physical or occupational therapy for burns involving the hands, feet, or joints.

## **Subsequent Visits**

- Follow-up weekly until the wound is epithelialized. Continue daily follow-up if compliance of patient or communication with provider is not optimal.
- Epithelialized wounds no longer need antibiotic ointments or dressings, but they do need daily sunblock (SPF 15 or higher) for 6 to 24 months to prevent hyperpigmentation. Once repigmentation is complete and the wound no longer blanches from red-pink to white with pressure, additional sunblock is not needed.
- Subsequent follow-up for at least 6 months and reevaluation every 4 to 6 weeks to check for hypertrophic scarring, which can occur up to 2 years after the burn.
- Hypoallergenic, unscented moisturizing creams (cocoa butter, mineral oil, or Vaseline Intensive Care lotion) for pruritus and xerosis. Antihistamines such as diphenhydramine or hydroxyzine pamoate.
- Patient education handout for home care. (See the patient education form available online at www.expertconsult.com.)

# Considerations for Referral to Burn Specialist or Surgeon

- Black people, who have increased risk of hypertrophic scars (if not healed at 10 days)
- Children and elderly (if not healed at 2 weeks)
- Adults (if not healed at 3 weeks)
- Wound infection
- Early hypertrophic scarring

<sup>&</sup>lt;sup>†</sup>See the "Considerations for Referral to Burn Specialist or Surgeon" section.

#### **PREVENTION**

- Encourage installation of smoke detectors on each floor of domestic dwellings, particularly at prenatal visits or well-child visits.
- Encourage parents to teach their children about the proper fire safety precautions, fire escapes, and the hazards of matches and fireworks.
- Encourage families to know and practice fire escape routes. Purchase rope escape ladders for bedrooms on the second floor.
- Advise smokers to quit smoking and not to smoke in bed.

#### **CONCLUSION**

Burns are a common problem, most of which can be managed in an ambulatory setting. An understanding of burn depth, high-risk burn locations, and how to estimate the burned percentage of TBSA is necessary for appropriate patient disposition. Understanding the potential complications and management principles for burn injuries permits early and appropriate medical and surgical therapy. Helping patients to understand how to care for their burn injuries and what complications to look for will further decrease the complication rates. For slowly healing wounds, surgical referral for excision and skin grafting can reduce healing time, contractures, and infection. Encourage good prevention practices.

#### **PATIENT EDUCATION GUIDES**

See the sample patient education form available online at www. expertconsult.com.

### **CPT/BILLING CODES**

16000 Burns, initial, superficial, when no more than local treatment required

16020 Burns, dressings and/or debridement of partial thickness, initial or subsequent, small (less than 5% TBSA)

Burns, dressings and/or débridement, medium

16030 Burns, dressings and/or débridement, large

16035 Burns, escharotomy, initial incision

16036 Burns, escharotomy, each additional incision

See Chapter 33, Skin Grafting, for procedural coding for skin grafts or skin substitutes.

## **ICD-9-CM DIAGNOSTIC CODES**

940.X Burn, unspecified

940–947.X Burns by specific site. Fourth digit of the code (0 to 5) indicates depth or severity.

948.XX

Burns classified according to extent of body surface involved. Fourth digit of the code indicates percentage of TBSA involved (0 = <10%, 1 = 10% to 19%, and so on up to 9 = 90% or more involved). Fifth digit of the code indicates percentage of TBSA involved in full-thickness burns.

## **CRYOSURGERY**

James W. McNabb • John L. Pfenninger

Cryosurgery is the deliberate destruction of diseased tissue by freezing in a controlled manner. It is important that all primary care physicians master the art and technique of cryosurgery. The procedure is often a better alternative than surgical excision, especially when convenience, healing, disability during healing, infectious disease risk (human immunodeficiency virus, hepatitis), discomfort, and scar formation are considered. (See also Chapter 138, Cryotherapy of the Cervix.)

#### **GENERAL CONSIDERATIONS**

- Lesions treated with cryosurgery usually heal with minimal or no scar formation. Even if inadvertent excessive freezing is done, scarring is rarely significant.
- Complete healing may take more than 6 to 8 weeks in extreme cases, but the results are usually excellent. Selective destruction of cells occurs during the freeze. However, the collagen and fibroelastic structural framework is preserved, so the epithelial cells grow back in an organized fashion within the preserved matrix.
- The procedure is safe, simple, and easy to learn. It usually takes less time than conventional surgery.
- Patients may prefer to avoid injections of local anesthetic, which is usually possible with cryosurgery.
- A burning sensation is experienced with the initial freeze and again on thawing. Explain to patients that the freezing will feel like an ice cube stuck to the skin. This often reassures them enough to cope with the minimal amount of pain experienced. However, young children often will not accept the procedure without crying. Their fear of the unknown increases when the unpleasant cold sensation starts. They have difficulty trusting that the burning feeling will actually improve in a very short time instead of continually getting worse. In children and in some adults, a local anesthetic will be helpful, especially when freezing multiple or large lesions and when attempting a deep freeze for malignant lesions.
- Other than keeping the lesions clean and protected, patients can
  essentially ignore the cryotreated lesion between treatments.
  They appreciate the omission of suture insertion and removal.
  Patients also welcome being able to bathe and swim while the
  lesion is healing.
- Secondary infection usually is not a significant problem. Even
  with overfreezing and with cryosensitive patients who overreact
  with excessive tissue destruction, infection occurs rarely. Excessive freezing may result in wound weeping for longer than 1 to 2
  weeks, but infection should not be expected unless the area
  receives poor skin care.
- Occasionally, a profuse watery discharge may persist more than 3 to 4 days after treatment. Débridement of the wound often alleviates the discharge.
- Two concerns exist regarding cryosurgery and use of the nitrous oxide closed system. The first is the spread of infectious agents by the equipment. Cryoprobes must be cleaned and sterilized between procedures using Cidex or an autoclave. Second, there

can be adverse health effects from prolonged exposure to nitrous oxide at high levels—far higher than will ever be experienced using nitrous oxide closed systems for cryosurgery for mere minutes at a time. Air hunger, dizziness, confusion, headaches, nausea, vomiting, and loss of consciousness or death may occur if nitrous oxide is present in quantities sufficient to dilute the oxygen concentration in the air. This overexposure creates an altered (euphoric or excited) mental state. Long-term exposure to nitrous oxide has been associated with neuropathy, increased rates of spontaneous abortion, and congenital anomalies in offspring. Federal regulations require nitrous oxide gas to be vented outside of the examination/treatment room. This can be accomplished by simply extending the exhaust tube on the unit out a window or by installing vents in an outside wall. The likelihood of a patient receiving enough exposure to do harm is very small and has not yet been reported. In practice, considering the minimal amounts of nitrous oxide used, few practitioners "vent" the rooms. Carbon dioxide (which is an agent nearly as cold) can be substituted for nitrous oxide, if a closed system is desired.

# ADVANTAGES OF CRYOTHERAPY (CRYOSURGERY)

- Local anesthesia is optional, so needles can usually be avoided.
- Freezing usually produces only minimal pain.
- Final healing is cosmetically excellent, with minimal or no scarring.
- Minimal physician time is required, and the procedure is easy to learn.
- Preoperative skin preparation is not required.
- Multiple lesions can be treated quickly in one office visit.
- Postoperative infection is rare.
- No complicated postprocedure care is needed.
- No significant disruption of postprocedure activity is required.
- The procedure is ideal for patients with light-complexioned skin.
- The procedure is inexpensive and cost effective.
- A wide variety of lesions can be treated without significant exposure to blood-borne pathogens.
- Units are portable and can be taken to nursing home facilities when needed.
- Units are relatively inexpensive with low start-up costs.
- Units take up little space in the office.

## **DISADVANTAGES OF CRYOSURGERY**

- Use is limited in patients with darker skin because of pigment changes. Even with brief partial-thickness freeze technique, some melanocytes are destroyed and the healed cryolesion may be slightly lighter in color than the surrounding skin, even in fairskinned individuals.
- Cryosurgery is not recommended in areas of hair growth, such as around the eyebrows and eyelashes, and on scalps with thin hair, because even brief freezing tends to destroy hair follicles.

- Healed cryolesions may not tan sufficiently, often are more susceptible to sunburn, and may require added sunscreen protection.
- Tissue is not available for histopathologic diagnosis, so certainty
  of complete removal is lacking.
- There is the possibility of exposure to nitrous oxide gas if closed units are used (see earlier).

#### **AGENTS USED FOR CRYOSURGERY**

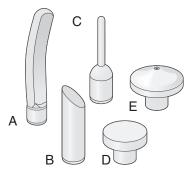

There are three basic methods of cryosurgery (Table 14-1).

- Closed systems (freezing is carried out with a cooled probe as opposed to the application of the agent itself)
  - Nitrous oxide
  - Carbon dioxide
  - CryoPen
- 2. Liquid nitrogen
  - Thermos bottle/spray unit (Brymill; Wallach)
  - Cotton-tipped applicators and Styrofoam cup
- 3. Aerosol canister
  - Tetrafluoroethane (Verruca-Freeze, Medi-Frig)
  - Ether/propane (Histofreezer)

Nitrous oxide is quite unstable, and once it is released into the probe, it immediately breaks down to molecular nitrogen and oxygen. The physical characteristics of the nitrous oxide gas enable the cryotip's temperature to be easily lowered to its boiling point of -89° C. With carbon dioxide, the tip is not as cold, and it will take slightly longer to achieve a quality freeze (-78.5° C).

Nitrous oxide comes in a closed gas cylinder (blue tank, versus brown for carbon dioxide and green for oxygen). The hand-held cryogun, which is connected to the tank with tubing, is structured differently from the liquid nitrogen guns. It is designed to allow a controlled, rapid expansion of nitrous oxide gas within the cryoprobe tip, lowering its temperature to -89° C. The storage tanks preserve nitrous oxide virtually "forever" by keeping the gas under pressure with no port for evaporation (except for cryogun activation). The tanks are moved from storage to use on small carts. The cryoprobes (tips) come in numerous shapes and sizes to match the lesion to be treated. The rounded, pointed, and slanted flat tips are popular for dermatologic applications (Fig. 14-1). The hemorrhoid tip is rarely, if ever, used for hemorrhoids, but its shape allows use for multiple dermatologic lesions. The flat and slightly conical 19and 25-mm tips that are used for cryosurgery of the cervix can also be used for dermatologic applications.

Because nitrous oxide does not achieve a probe temperature as low as liquid nitrogen (-89° C versus -196° C), it is significantly slower at freezing tissue. This is especially important when treating

**Figure 14-1** Sample of varying shapes of cryoprobe tips. Most come in variable sizes. **A**, Hemorrhoid tip. **B**, Slanted flat tip. **C**, Pointed tip. **D**, Flat cervical tip. **E**, Slight conical cervical tip.

multiple lesions. Both nitrous oxide and liquid nitrogen are effective for treating malignancies. Overlapping treatment areas for larger lesions using large probes ensures efficacy. Nitrous oxide units have an active defrost mode that rapidly frees the cryotip from frozen tissue.

CryoPen is a closed, self-contained refrigerant system. It uses an internal cryogen that is cooled in a free-standing unit to -95° C. It eliminates the handling of cryogen gases and liquids. CryoPen reusable tips are available in 3-, 5-, 7-, and 10-mm sizes. These are applied directly to the lesion and maintained in place until the clinical end point has been reached.

Liquid nitrogen is the coldest cryogen, effecting a rapid, deep freeze (boiling point –196° C). A large storage container (Dewar) is needed. Newer Dewars can store the liquid nitrogen for up to 1 year. Liquid nitrogen is relatively inexpensive, but if not used it will evaporate. Liquid nitrogen may be applied to the lesion directly using cotton-tipped applicators or sprayed using a thermos-type unit (Brymill CRY-AC and CRY-AC-3 [Brymill Cryogenic Systems, Ellington, Conn], or Wallach UltraFreeze [Wallach Surgical Devices, Orange, Conn]). The various apertures of the spray tips allow a variable amount of gas to cover a lesion, allowing control over the extent of freezing. A reusable plastic shield is available to limit gas spread. These spray units allow efficient and rapid treatment of multiple lesions in a single office visit. Additional probes are available that allow the thermos to be used as a closed system, but there is no active defrost. Subsequently, the tip may "stick" to the tissue for a significant length of time before it thaws and detaches.

Canister refrigerants are the least expensive agents used for cryosurgery. They come prepackaged in small hand-held canisters the

	Agents Agents				
Characteristics	Liquid Nitrogen	N <sub>2</sub> O	CO <sub>2</sub>	Tetrafluoroethane	Ether/Propane
Boiling point	−196° C	−89° C	−78.5° C	−47° C	−25° C
Effective treatment temperature	−196° C	−89° C	−78.5° C	−70° C	–55° C
Use	Thermos-type guns Cotton-tip applicator Stored in large Dewars	Cylinders with applicator gun (cryoprobe)	Cylinders with applicator gun (cryoprobe) Dry ice slush	Aerosol canister	Aerosol canister
Method/system	Open/closed	Closed	Closed/open	Open (spray/cones, buds)	Open (buds)
Shelf life	I yr max. with best Dewars	Indefinite	Indefinite	5 yr	5 yr +
Flammable	No	No	No	No	Yes
Trade name	Cryogun (Brymill Cryogenic Systems) UltraFreeze (Wallach)	_	_	Verruca-Freeze (CryoSurgery) Medi-Frig (Ellman International)	Histofreezer (OraSure Technologies)
Indications	All	All	All	Superficial only (no cancers)	Superficial only (no cancers)

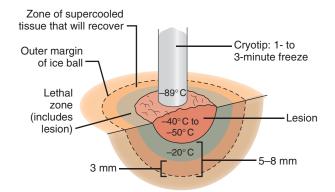

size of a soda can, making them portable for use in nursing homes, satellite clinics, and multiple examination rooms. They have a very long shelf life. Unfortunately, they do not achieve tissue temperatures low enough to treat very many lesions. These agents are not indicated for malignancies, deep lesions, or large lesions. *Trifluoroethane/pentafluoroethane/tetrafluoroethane* (Verruca-Freeze [CryoSurgery, Nashville, Tenn; Medi-Frig [Ellman International, Oceanside, NY]) is a nonflammable compressed gas that freezes tissue on vaporization (boiling point –47° C). *Dimethyl ether/propane/isobutane* (Histofreezer [OraSure Technologies, Bethlehem, Penn]) also comes in a canister but is not as cold (–25° C) and is flammable.

Over-the-counter skin refrigerants were approved for use by the U.S. Food and Drug Administration in 2003. Several products are available, including Dr. Scholl's Freeze Away, Wartner Plantar Wart Removal System, and Compound W Freeze Off. The first two products contain dimethyl ether and propane. Wartner's product also adds isobutane to these. Although the manufacturers state that temperatures as low as  $-57^{\circ}$  C are achieved on skin application, such low temperatures were not realized in a recent study. There is significant concern regarding their ability to create local tissue necrosis because of their inability to reach low temperatures rapidly enough to achieve clinical effect. In contrast to other physician-applied options, these over-the-counter products are also dangerous because they are extremely flammable.

#### **TISSUE EFFECTS: PRINCIPLES FOR TREATMENT**

It is important to recognize that at  $-2.2^{\circ}$  C, cells begin to freeze. At  $-5^{\circ}$  C, cells will supercool, but they recover. Tissue destruction begins only when the temperature is between  $-10^{\circ}$  C and  $-20^{\circ}$  C. A deeper freeze with temperatures between  $-40^{\circ}$  C and  $-50^{\circ}$  C ensures that malignant cells are completely destroyed.

The size of the ice ball that forms around the lesion provides a good estimate of the depth of the freeze. The lethal zone (tissue temperature less than  $-20^{\circ}$  C) is 2 to 3 mm *inside* the outer margin of the ice ball (Fig. 14-2). This is especially crucial to remember in cases of premalignant or malignant lesions, which are deeper in the skin. The size of the ice ball beyond the lesion is the most important criterion in determining how long to freeze. Factors requiring prolonged freeze time include low tank pressure, increased tissue vascularity, excessive overlying keratin (needs to be removed or moistened), and poor tip-to-lesion contact. The use of different systems (e.g., nitrous oxide, liquid nitrogen, carbon dioxide, canister gases) dramatically affects the rapidity and depth of freeze. Likewise, the method of applying liquid nitrogen (with the cotton-tipped applicator or in a spray fashion) affects freezing parameters. Once an ice ball of the desired size has been obtained, it is just as important to observe the time it takes for the area to thaw from the outer edge of the ice ball

**Figure 14-2** Nitrous oxide full-thickness destruction freeze technique (malignant lesions). Note that the outer supercooled area will recover. Monitoring thaw times for both malignant and benign lesions is extremely important (see Box 14-1).

## Box 14-1. Freezing Guidelines for Skin

#### Benign Lesions

- Ice ball 2 mm beyond lesion borders.
- Correlate with thaw times (see below).
- Consider double freeze for difficult and/or premalignant lesions.

#### Malignant and Most Premalignant Lesions

- Ice ball 5 mm beyond lesion borders.
- Double freeze (freeze, thaw, refreeze, using same parameters).

#### Freeze Time

- Variable, depending on cryogen, pressure applied, size of lesion, type of lesion, size of nozzle/tip, expertise of operator.
- Second freeze is faster.

#### Halo Thaw Time

- 1 min (benign).
- 2–4 min (malignant).

#### Total Thaw Time

- 2–3 min (benign).
- 3–5 min (malignant).

#### Liquid Nitrogen

- Small swab (small lesions) and large swab (large lesions).
  - 10-sec freeze.
  - Total thaw time: 60 sec (superficial lesions).
- Spray: as noted above for other applications.

See text for details and for specific lesions.

to the lesion edge ("halo thaw time") and the time for all the tissue to thaw (total thaw time; Box 14-1). A brief freeze can turn tissue white, providing the ice ball desired; however, if it remains frozen only momentarily, it will have little effect.

Freeze times should be adjusted according to patient sensitivity, type and size of the lesion, presence of malignancy, and lesion vascularity. Table 14-2 shows the variations with nitrous oxide alone,

## **TABLE 14-2** Freeze Time Guidelines for Nitrous Oxide Technique

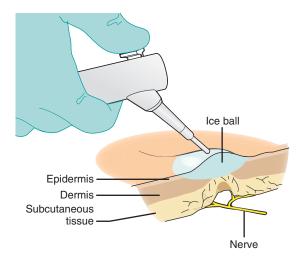

Oxide recinique		
Tissue	Lesion	Freeze Time*
Skin	Full-thickness, benign Full-thickness, malignant Plantar warts (after débridement) Condylomata Verrucae Vascular lesions (with pressure) Seborrheic keratoses (2-mm margin) Actinic keratoses (3-mm margin)	I-I.5 min I.5-3 min <sup>†</sup> 40 sec 20-45 sec I-I.5 min I-I.5 min 30 sec <sup>†</sup> I-I.5 min <sup>†</sup>
Vascular	Basal cell cancer (3- to 5-mm margin) Hemorrhoids	1.5 min <sup>†</sup>
vascalai	Cryoligation Cryo without ligation	2 min 2–3 min <sup>†</sup>
Cervix	Cervicitis Cervical intraepithelial neoplasia I, II, III Cervical intraepithelial neoplasia I, II (alternative method)	3 min 3 min <sup>†</sup> 5 min

\*Freeze times are approximate guidelines and should be adjusted to the size of the ice ball and the thaw time, which are far more important than the freeze time alone. Because nitrous oxide is slower and more controlled, freeze times are more reliable than with liquid nitrogen.

<sup>†</sup>Freeze-thaw-refreeze.

<b>TABLE 14-3</b>	Freeze Time Guidelines for Liquid	d
Nitrogen C	pen-Spray Technique	

Lesion	Common Freeze Time in Seconds
Actinic keratoses	5–15
Cherry angioma	5–10
Condylomata	5–10

Molluscum contagiosum	5–10
Mucocele	10–30
Papilloma	5–10
Prurigo nodularis	10–30
Sebaceous hyperplasia	5–10
Seborrheic keratoses	10
Skin tags	5–10
Common warts	10–20

**Figure 14-3** With nitrous oxide, once the cryotip is frozen to the skin, the probe can be retracted to avoid freezing nontarget underlying structures.

and Table 14-3 shows those with liquid nitrogen. Age, vascular flow, amount of pigment, depth of lesion, amount of keratin, location on the body, and cell type of the lesion all affect the amount of freezing required to destroy pathologic tissue. Adjust your freeze times accordingly. Applying pressure to the lesion with the fixed probes will increase the depth of freeze. Vascular lesions will require longer freezing times, and pressure from the probe should be applied to squeeze as much blood as possible out of the lesion before freezing. Any active bleeding from a prior shave or curettement will need to be controlled first.

For *benign lesions*, a single freeze/thaw cycle is sufficient. The ice ball should extend 2 to 3 mm beyond most lesion margins. Resistant lesions such as warts often require a freeze/thaw/freeze cycle. Complete thaw times should be 2 to 3 minutes for larger lesions.

For malignant or premalignant lesions, a freeze/thaw/freeze cycle is recommended. The ice ball should extend 5 mm beyond the lesion margin each time the tissue is frozen. The second freeze is usually quicker and less painful.

Dry, keratinized tissue will not freeze easily and insulates the lesion underneath from freezing. Remove as much keratin as possible before freezing, especially when using nitrous oxide, carbon dioxide, or the canister agents.

With the nitrous oxide cryotips, once the tip is "frozen" and fixed to the skin, the probe can be pulled back, tenting up the skin, to reduce the depth of freeze, thereby sparing deeper critical structures (such as nerves) from exposure to freezing (Fig. 14-3).

Bandages are not necessary unless the lesion is continually irritated (i.e., by clothing), develops a large blister, or develops a serous discharge.

#### POST-TREATMENT PHYSIOLOGIC EFFECTS

Erythema and hyperemia are immediate responses to effective freezing. Edema and exudation (blister formation) peak within 24 to 48 hours and usually subside after 72 hours (Fig. 14-4). Blood may accumulate under the blister, making it appear black (Fig. 14-5). The extracellular collagen structures are more resistant to freezing than the cells themselves. Crust formation begins, and this crust will slowly contract over the next several days. Reepithelialization occurs from the outer margin inward. Fibroblasts lay down minimal new collagen along the preserved, well-formed collagen matrix, resulting in a lack of scar formation. If the collagen matrix has been destroyed by excessive cryoinjury, fibroblasts will produce collagen randomly, leading to scar formation (Fig. 14-6). Cartilage (e.g., in the ear) is preserved.

Figure 14-4 A, A 10-cm hypertrophic scar over upper abdomen. B, Application of nitrous oxide probe. C, Appearance immediately after thawing. D, Blister formation at 5 hours. E, Ruptured blister at 4 days. F, Appearance at 11 days. G, Final appearance after a second cryotherapy treatment several months later; the small residual scar resolved after the third focal treatment.

**Figure 14-5** Appearance of a hemorrhagic bulb after cryotherapy of a plantar wart.

If the patient or physician desires, the treated lesion can be surgically débrided in 24 to 48 hours. During this time, the dermis and epidermis separate, lifting the lesion to the top of the blister. Removal of the prepared lesion with iris scissors is painless. After 72 hours, however, the lesion may stick like a graft and may bleed on attempts at removal. If completely left alone, the lesion will eventually slough spontaneously. (Surgical débridement 1 or 2 days after freezing effectively removes the lesion and satisfies some patients sooner. However, many patients are quite happy to avoid the early return visit and are willing to wait to see how much of the lesion sloughs before returning for another treatment.) A disadvantage of this technique is that a second office visit is needed for the 24- to 48-hour débridement procedure, and the serous discharge without the intact blister can be quite copious depending on the size of the lesion.

The healed cryolesion is soft, with minimal to no scarring. This allows erections if penile lesions have been frozen. Pigment is often decreased, and hair and sweat glands may be destroyed in the area of freezing. It is best to caution the patient *in advance* that although the area that was frozen is unlikely to develop much of a scar, the skin is often lighter. The inflammatory response may result in the development of a transient halo of hyperpigmentation. This will usually clear completely over several months.

## **INDICATIONS**

- Actinic keratoses (full-thickness freeze)
- Angiomas or hemangiomas, including congenital strawberry hemangiomas (more difficult)
- Basal cell carcinoma (full-thickness destructive double-freeze)
- Bowen's disease (squamous cell carcinoma in situ)
- Cervical intraepithelial neoplasia (CIN, dysplasia), "cryoconization" (see Chapter 138, Cryotherapy of the Cervix)
- Chondrodermatitis helicis nodularis
- Condylomata acuminata
- Dermatofibromas (difficult)

**Figure 14-6** Excessive scarring (rare) after cryosurgery of verrucous lesion over first metatarsophalangeal joint of the large toe on the left foot.

- Freckles (lentigines)
- Granulation tissue
- Hemorrhoids (rarely done)
- Hypertrophic scars (often multiple treatments over time)
- Keloids (as for hypertrophic scars)
- Lentigos
- Molluscum contagiosum
- Mucocele
- Myxoid cysts
- Papular nevi (full-thickness freeze)
- Pyogenic granuloma
- Squamous cell carcinoma (full-thickness destructive double-freeze)
- Seborrheic keratoses (procedure of choice)
- Skin tags and polyps
- Verrucae (including plantar)
- Xanthoma

#### **CONTRAINDICATIONS**

#### **Absolute Contraindications**

- Proven excessive reaction to cryosurgery
- Patient nonacceptance of the possibility of skin pigment changes
- Malignant melanoma
- Areas of end-stage compromised circulation
- Lesions in which identification of tissue pathology is required
- Sclerosing (morpheaform) or recurrent basal cell or squamous cell carcinoma

#### **Relative Contraindications**

- Basal cell or squamous cell carcinomas more than 1 cm in diameter
- Any condition with high levels of cryoglobulins (most are noted in this list)
- Immunoproliferative neoplasms (e.g., myeloma, lymphoma)
- Macroglobulinemia
- Active severe collagen vascular diseases
- Severe active ulcerative colitis
- Acute poststreptococcal glomerulonephritis (almost 100% of these patients have high levels of cryoglobulins)
- Active subacute bacterial endocarditis, syphilis, Epstein-Barr virus infection, cytomegalovirus infection
- Chronic severe hepatitis B
- High-dose steroid therapy

NOTE: The majority of patients with the preceding conditions are likely to have an exaggerated response to cryosurgery because they have high levels of circulating cryoglobulins. If cryosurgery is appropriate or necessary for any of these patients, be sure to obtain informed consent and perform a pretest in the axilla or thigh area before treating a more prominent or cosmetically sensitive area. Proceed with caution and greatly shorten the freezing times until the response can be predicted. You may be able to freeze lesions effectively and safely with a much shorter freeze time. With overfreezing, the risk of tissue slough and marked hypopigmentation increases. Therefore, start slowly and advise patients that extra visits and treatment sessions may be necessary. A conservative approach is best in light of their clinical situation.

## Lesions Difficult to Treat with Cryosurgery

- Dermatofibroma (these lesions require a longer freeze time)
- Hidradenitis
- Flat nevi (must be absolutely sure the lesion in not a melanoma)
- Squamous cell cancer (usually reserved for practitioners who treat this cancer often)
- Most vascular lesions (especially if extensive)

Figure 14-7 A, Brymill CRY-AC cryoguns are refillable with liquid nitrogen. B, Wallach UltraFreeze Cryosurgical System. C, Liquid nitrogen Dewar. D, Brymill open-spray aperture tips (openings of tip vary in size, with "A" the largest). E, Brymill closed miniprobes. (A and C–E, Courtesy of Brymill Cryogenic Systems, Ellington, Conn. B, Courtesy of Wallach Surgical Devices, Orange, Conn.)

## **Areas Not Recommended for Cryosurgery**

- Areas where hair loss is critical to the patient
- Areas where pigment changes are critical to the patient
- Feet, ankles, and lower legs, when circulation is in question (especially patients with diabetes or peripheral vascular disease)
- Over superficial cutaneous nerves (unless adequate skin traction to pull the skin away from the nerve is possible, usually with nitrous oxide technique)
- Basal cell cancers in the nasolabial fold, in preauricular areas, and on lips (often more extensive and tend to recur)
- Any cancer that has not had histologic confirmation
- Periorbital area (may induce immediate and severe swelling)
- Port wine stain (use laser)

## **EQUIPMENT**

## Liquid Nitrogen

- Cryogen spray unit (Fig. 14-7A and B)
- Storage Dewar (Fig. 14-7 C)
- Assorted various-sized nozzles (Fig. 14-7D and E)
- Protective plastic shield with assorted opening sizes (Fig. 14-8)
- Styrofoam cups (if thermos canister is not available)

- Cotton-tipped applicators (small and large)
- Metal pickups (optional; Fig. 14-9)

#### **Nitrous Oxide**

- 20-lb tank (the "short, fat, blue one"; Fig. 14-10A)
- Mobile storage cart (see Fig. 14-10A)
- Cryoprobe regulator with gun (Fig. 14-10B)
- Cryoprobe tip assortment (Fig. 14-11)
- K-Y Jelly or cryogen gel; do not use anything that is not water soluble (e.g., petrolatum)

## **Canister Gas Refrigerants**

- Can of Verruca-Freeze (Fig. 14-12A) or Medi-Frig (Fig. 14-12B) with various sizes of plastic limiting cones and buds (see Fig. 14-12A and C)
- Can of Histofreezer with applicators

## **CryoPen**

- CryoPen base unit (Fig. 14-13)
- CryoPen reusable tips (3-, 5-, 7-, and 10-mm sizes)

**Figure 14-8** Protective shield (Brymill) with various-sized orifices, which limits the spread of open-spray liquid nitrogen and protects surrounding skin.

**Figure 14-9** Special cryosurgical forceps (Brymill) with extra mass at tips to allow freezing of multiple lesions before recooling. No anesthesia is needed.

**Figure 14-10 A,** Nitrous oxide cryosurgical unit. Handpiece is placed in holder and connected to a 20-lb tank. **B,** Leisegang cryosurgical hand gun.

**Figure 14-11** Various cryosurgical tips for treatment of a variety of dermatologic lesions with nitrous oxide. *Left to right:* Fine point, small cup, round tip, hemorrhoid tip, and slightly coned tip. (Also see Chapter 138, Cryotherapy of the Cervix.)

Figure 14-13 CryoPen base unit.

Figure 14-14 Liquid nitrogen applied directly to a skin lesion using the dipstick technique.

#### PREPROCEDURE PATIENT PREPARATION

Before the procedure, the patient should be advised of the basic technique, the expected sensation during treatment, and the possible complications. The advantages of and rationale for using cryosurgery also should be reviewed with the patient.

For all methods listed, consider local anesthesia for patient comfort and the ability to freeze long enough to obtain the desired effect. The need for anesthesia will depend on the size of the lesion, number of lesions, patient age, and other factors.

## **TECHNIQUE**

### Liquid Nitrogen

## Cup/Cotton-Tipped Applicator or Metal Pickups Technique

- Dispense a small amount of liquid nitrogen into a Styrofoam cup to prevent contaminating the primary source of liquid nitrogen.
- 2. Choose the size of the cotton-tipped applicator to match lesion.
- 3. Dip a clean cotton-tipped applicator into the cup and then touch the lesion with the applicator.
- 4. Keep the applicator cold by dipping it into the cup every several seconds and reapplying to the lesion to obtain the desired size of ice ball (Fig. 14-14). Do not place a cotton-tipped applicator that

- has touched the patient, or the treatment cup supply, into the primary source of liquid nitrogen because contamination can occur. Likewise, do not return any unused liquid into the Dewar. Viruses often are not killed by the cold and may be spread to others if contamination of the source occurs.
- 5. The size of the applicator and amount of pressure applied affect rapidity and depth of freeze.
- Freezing times are markedly shortened with liquid nitrogen. The
  cotton-tipped applicator/cup method is not as fast as the cryogun,
  but it is still significantly faster than nitrous oxide and can be
  used readily for small lesions, if benign or premalignant (e.g.,
  actinic keratosis).
- 7. A variant of the foregoing method can be used for pedunculated lesions such as skin tags. Metal needle drivers or metal pickups are dipped into the cup of liquid nitrogen. The lesions are then grasped. This technique limits the spread of the freeze and is very effective (Fig. 14-15).

## Spray Technique Using a Cryogen Spray Gun: Brymill CRY-AC or Wallach UltraFreeze

The timed-spot freeze technique allows standardization of liquid nitrogen delivery.

- 1. Select the nozzle size. The "C" tip is the one chosen most commonly for use with the Brymill; this size is a starting point. Although the "D" has a smaller opening, the "B" tip has a larger orifice and can treat large lesions faster. The "A" tip is larger still (Fig. 14-7D).
- Position the nozzle of the spray gun perpendicular to the lesion, 1
  to 1.5 cm from the skin surface and aimed at the center of the
  target lesion (Fig. 14-16A). A tangential spray can be used to
  create a slower, more controlled freeze.
- 3. Spray the lesion. The spray gun trigger is depressed and liquid nitrogen is sprayed until an ice ball encompasses the lesion and the desired margin (see Box 14-1). The spray needs to be maintained in either a continuous or intermittent fashion to keep the target field frozen for an adequate time. This time may vary from 5 to 30 seconds. Spraying intermittently will keep the ice ball smaller. If more than one freeze/thaw cycle is required for lesion destruction, complete thawing should be allowed before the next cycle is started (usually 2 to 3 minutes; see Table 14-3).
- 4. Little movement of the gun is needed unless the lesion is large (>2 cm). Usually it is a direct spray technique as described previously. For large lesions, overlapping direct sprays can be

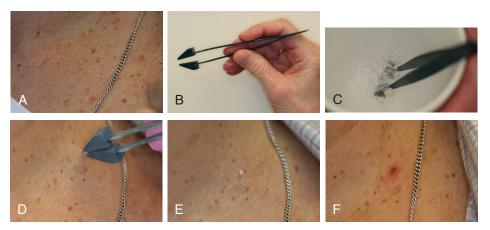

Figure 14-15 The treatment of a skin tag using cryosurgical forceps. **A**, Skin tag. **B**, Forceps. **C**, Forceps in Styrofoam cup with liquid nitrogen. **D**, Grasping the skin tag for a few seconds. **E**, Frozen tag. **F**, Appearance of tag 10 minutes after freezing.

Figure 14-16 A, Perpendicular spray technique using liquid nitrogen in a cryogun. B, Open spray using a spiral pattern to cover a large area. C, Cryosurgery of a wart using the Brymill CRY-AC with a closed probe.

- performed, or the lesion can be covered in a paintbrush or enlarging spiral pattern (Fig. 14-16B).
- 5. Using a limiting cone or plastic plate shield with variable-sized openings (see Fig. 14-8) is recommended for most smaller lesions because it focuses the spray onto the area desired and limits destruction of normal tissue. It is also helpful around critical areas like the eyes to limit the spread of the spray. Hold it tight against the skin to prevent leakage. Select the cone size to give the desired size of ice ball. The ice ball will still usually spread 1 to 2 mm beyond the size of the opening. Use freezing guidelines (see Box 14-1) for desired effect.

Liquid nitrogen spray techniques achieve desired freezing levels 8 to 10 times faster than nitrous oxide.

#### **Contact Probes**

Small, solid tips much like the nitrous oxide tips also can be used with the thermos guns, but the diameters are only 2 to 4 mm (Fig. 14-7E).

- 1. Select the appropriate size and apply the probe tip directly to the skin or lesion (see Fig. 14-16C).
- 2. Obtain the rim of ice ball size desired.
- 3. Allow to thaw.

The advantage of these tips is that the ice ball is well controlled and forms much faster than with nitrous oxide. They can also be used in areas such as around the eyes where it is necessary to avoid a wider spray. The disadvantage of using these probes is that the thawing is passive and can take a long time. Although large tips have been designed to apply to the cervix for dysplasia, studies proving adequacy are not available.

## CryoPen Closed System

- 1. Select the appropriate size reusable tip to match the lesion.
- 2. Apply the CryoPen tip directly to the lesion.
- 3. The size of the tip and amount of pressure applied affect rapidity and depth of freeze.
- 4. Obtain the rim of ice ball size desired.
- 5. Allow to thaw.
- 6. Repeat the freeze if indicated.

The advantage of these tips is that the ice ball is well controlled. They can also be used in sensitive areas such as around the eyes where it is necessary to avoid cryogen spray.

## Nitrous Oxide or Carbon Dioxide Closed System

- 1. Débride any keratin you can beforehand (e.g., plantar wart). This is usually done using a blade and shaving away any callus.
- 2. Place a thin layer of water-soluble gel on the lesion to hydrate the lesion and to enhance even contact with the cryoprobe. If the lesion is dry, soaking it well with a wet 4 × 4 gauze pad before application of the gel will enhance the effectiveness of the freeze, especially if it is a large lesion.
- 3. *Select a probe* with a size and shape that correspond to the lesion size (Fig. 14-17).
- 4. Hold the handpiece ("gun") with trigger in one hand, and *guide* the probe tip to a point over the site of freezing (see Fig. 14-17).
- 5. Place the tip on the lesion and activate the gun. The tip will stick to the skin within 3 to 5 seconds.

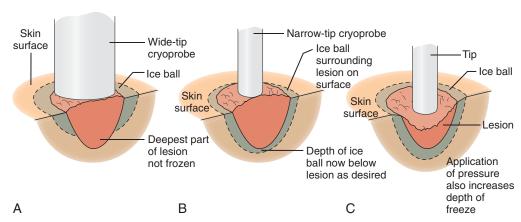

Figure 14-17 Cryosurgery of a deep but narrow lesion. **A,** If a wide cryoprobe tip is used, the deepest part of the lesion will not be frozen even though a 3- to 5-mm margin of ice ball is obtained. **B,** To ensure that the entire lesion is frozen, a tip smaller than the lesion may be used, thereby limiting the rapid lateral spread of the ice ball. **C,** Alternatively, the cryoprobe tip may be pressed down until the top of the lesion is below the skin surface. The cold will penetrate deeper before too much normal tissue is frozen by lateral spread.

**Figure 14-18** Cryosurgery of a lip lesion using a nitrous oxide closed system with a "hemorrhoid tip." **A,** Freezing the lesion. **B,** Appearance immediately after removing the tip.

- 6. Freeze until desired ice ball is obtained (Fig. 14-18A).
- 7. Thaw. This will be an active process. Some units will thaw automatically when the freeze trigger or button is released, whereas others require that a second button be pushed. The gas from the tank to the handpiece must be turned on for this to occur! The tip will "release" from the skin within seconds. The frozen skin will then thaw passively (Fig. 14-18B).

## Cryogen Canister: Verruca-Freeze/Medi-Frig or Histofreezer

See Figure 14-12.

- 1. Select a limiting cone size that will completely encompass the lesion (which must be benign) plus 2 mm of normal tissue.
- 2. Hold the cone securely against the skin to prevent leakage (essential! see Figs. 14-12C and 14-17A).
- Dispense enough liquid from the canister to fill the cone to the line (approximately 1/8 to 1/4 inch). Avoid splattering; use a gentle spray.
- 4. Allow the fluid to evaporate (30 to 60 seconds).
- 5. Remove the cone.
- 6. Repeat, if indicated.

Alternatively, the buds can be frozen and then applied to the lesions much like the cotton-tipped applicators with liquid nitrogen.

## **TECHNIQUE FOR SPECIFIC LESIONS**

## **Keratin Removal**

Lesions with dense keratin coverings (e.g., plantar warts) are very resistant to cryosurgery (especially to nitrous oxide and canister gases). The patient can help prepare a plantar wart with 2 weeks of salicylic acid application: After bathing and cleaning the area, the patient should apply a 17% solution (Compound W) to the wart(s). A piece of Mediplast (40% salicylic acid) or Trans-Ver-Sal, cut just a little larger than the wart, can also be used. This is left in place 24 hours until the next day's application. (If the pad migrates significantly during the day, it may be used at night only.) After 2 weeks, a soft white layer of keratin can be peeled away, revealing the base or root of the plantar wart lesion. Freezing time for the lesion should be shortened once the keratin layer and outer epidermis have been removed.

Alternatively, in lesions with significant keratin, a no. 10 or no. 15 scalpel blade can be used to shave off the keratin in thin layers until the first red punctate vasculature is seen (verruca). Stop débridement at this point (punctate bleeding) to minimize bleeding.

#### **Actinic Keratoses**

Usually actinic keratoses are quite superficial. If they are numerous, liquid nitrogen is much quicker to use than nitrous oxide. Anesthesia is rarely needed. Because these lesions are premalignant, however, a full-thickness freeze is suggested. Whichever technique is used, be

sure to obtain at least a 3-mm ice ball. It may be best to freeze a second time. Moisten the lesion first (with K-Y Jelly) if nitrous oxide is used.

#### Nonmelanoma Skin Cancers

This technique is used for treating malignant lesions such as basal cell carcinomas less than 1 cm. Be sure to confirm the diagnosis by obtaining a biopsy specimen before treatment. Many physicians do not use cryosurgery on malignancies other than basal cell carcinomas, although studies would support treating smaller (<1 cm) squamous cell carcinomas also. Malignant cells are more cryoresistant, and destruction requires temperatures of -40° C to -50° C. Only liquid nitrogen or nitrous oxide may be used to treat malignancies. The canister cryogens do not achieve low enough tissue temperatures for effective treatment of these lesions. If cryosurgery is the chosen method of destruction for basal cell carcinoma, the probe can be applied directly to the lesion. Alternatively, shave off (debulk) most of the lesion and freeze the now thinned-out residual. Follow the steps outlined previously for the technique used, but continue the freeze until the ice ball is 5 mm beyond the margins of the lesion (see Fig. 14-2). When freezing is complete, allow the lesion to slowly completely thaw and repeat the freezing process a second time. Because a malignancy is being treated, it is wise to document the extent of the freeze and the thaw time. Freeze time will vary depending on the cryogen being used, but the thaw times should be the same—halo thaw time about 2 minutes with complete thaw time 3 to 5 minutes, depending on size (see Box 14-1).

## Full-Thickness Freeze Technique for Anatomically Large or Irregular Skin Lesions

Some lesions are too large to be completely frozen by a cryoprobe in a single freeze. Some examples are Bowen's disease, keloids, vascular lesions, or mosaic warts. In such cases, note the central location of the cryoprobe. This spot will be the lateral margin of the cryoprobe placement (nitrous oxide) for the next adjacent freeze (after thawing occurs). This allows for the 50% overlap that is desired. Freezing of extremely large lesions can begin on one side, and then the opposite side can be frozen while the first is thawing. Progressing from opposite sides to the center will save time and still allow for a 40% to 50% freeze overlap.

Using liquid nitrogen, overlapping direct sprays can be performed or the lesion can be covered in a paintbrush or enlarging spiral pattern. It is important that a good freeze be obtained over the entire lesion.

#### **Hypertrophic Scars and Keloids**

Cryosurgery can be used in two different ways to treat scars. It can be used alone or before injection of steroids. The hyperemia and edema that immediately follow freezing and thawing soften the hypertrophic scar or keloid and allow easy penetration by a needle and a more even distribution of intralesional steroid. Cryosurgery alone, without steroids, will reduce the size of large keloids, but numerous treatments may be needed and more vigorous freezing is needed if steroids are not used (also see Chapter 38, Hypertrophic Scars and Keloids).

Use the following technique for nitrous oxide (see Fig. 14-4):

- 1. Select a cryotip slightly narrower than the scar. You do *not* want the ice ball to extend more than 1 mm beyond the scar.
- 2. Apply a thin coat of water-soluble gel to the scar only. (Do not cover any of the surrounding skin.)
- 3. Moisten and warm the cryotip in warm water. Freeze until the ice ball progresses just to the edge of the scar, usually for 20 seconds to 1 minute, occasionally longer if necessary.
- 4. If steroids will be used, wait approximately 10 to 15 minutes for mild tissue swelling, then proceed with intralesional injection using triamcinolone diacetate (Aristocort) or triamcinolone acetonide (Kenalog 10 mg/mL) with a small 30-gauge needle. Use very dilute solutions (0.1 mL diluted with 0.3 mL of a parabensfree 1% lidocaine without epinephrine) and a sufficient volume to infiltrate the entire scar. (Increase the concentration on successive visits as necessary, depending on response.)
- 5. For large scars, four to five treatments may be necessary at 6- to 8-week intervals to achieve optimal success.

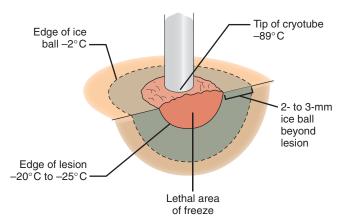

Liquid nitrogen can also be used. It is quicker and very efficacious, but it may be more difficult to limit the size of the freeze with smaller lesions.

Treatment may produce a copious discharge during the first few postoperative days.

## Condylomata Acuminata

See also Chapter 155, Treatment of Noncervical Condylomata Acuminata.

- 1. Penile, perianal, and vulvar areas are sensitive. Individual lesions and small groups of condylomata can be frozen without anesthetic. Topical anesthetics can also be applied before freezing. In some situations, 20% topical benzocaine (Hurricaine), 5% lidocaine, EMLA cream, or ELA-Max may be appropriate. Topical applications may require 30 to 60 minutes to achieve maximum effectiveness. ELA-Max is now available over the counter. Large or multiple lesions may require injections of local anesthetic.
- 2. Find all the lesions. For women, examine the genitalia and the cervix with a colposcope to look for very small lesions, particularly in the vaginal introitus, on the vaginal side walls, the vulva, and the rectum. Women with external condylomata have a high incidence of cervical dysplasia, and colposcopy may be indicated. (See Chapter 137, Colposcopic Examination, and Chapter 138, Cryotherapy of the Cervix.)
- 3. If nitrous oxide is used, moisten the skin lesions with a water-soluble gel. Touch the lesion(s) with an appropriately sized probe. Activate the nitrous oxide–powered tip, and effect adherence after 3 to 5 seconds. Then apply gentle traction. Do not pull too hard or you may tear the tissue being treated or the surrounding skin. Freeze for approximately 20 to 45 seconds. Judge actual freezing time by the size of the lesion and the ice ball, which should extend 2 mm beyond the margin of the lesion(s) (Fig. 14-19). Within minutes after freezing, the condylomata darken and then will turn black; they should slough within a few days. If they do not turn dark, refreezing may be necessary.
- Liquid nitrogen in either form (spray, cotton-tipped applicator, or metal pickups) is quicker for treating multiple lesions. Needle drivers dipped into a cup of liquid nitrogen will also work.
- 5. A combination of electrosurgery (radiofrequency surgery) and cryosurgery may speed the treatment of extensive perianal, vulvar, or penile lesions. The cryosurgery component will allow preservation of the elastic tissue matrix and expandability of the

**Figure 14–19** Treatment of benign lesions. To ensure that all of the tissue of the lesion reaches the  $-20^{\circ}$  C to  $-25^{\circ}$  C necessary for destruction, the outer edge of the frozen area (the ice ball) should extend at least 2 to 3 mm in all directions beyond the lesion.

anal canal, penis, and vulva after healing. The electrosurgery component is used for tissue débridement, making sure not to cut too deep. Then, the base of each lesion is frozen for 20 to 30 seconds. This technique can be used for treatment of large areas of condylomata often seen on the genitalia.

## **Molluscum Contagiosum**

Freezing is often an excellent, nearly painless treatment for molluscum contagiosum. Advise your patients, particularly children, to protect the healing crust to decrease the chance of scar formation.

- 1. If using nitrous oxide, prepare each lesion with a small amount of water-soluble gel. Freeze each lesion for 30 seconds to 1 minute. Use very fine-tipped probes to avoid freezing normal skin.
- With liquid nitrogen, only brief freezes of several seconds are necessary.
- 3. Advise the patient and parent that the lesions should fall completely off within 2 weeks or less. If they do not, the patient should return soon for retreatment to prevent their spread.

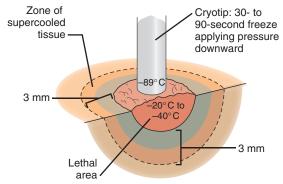

## Vascular Lesions (Hemangiomas and Strawberry Hemangiomas)

As with malignant lesions, vascular lesions are more cryoresistant, and a freeze/thaw/refreeze technique is recommended (Fig. 14-20). Nitrous oxide may be the preferred method both to control the extent of the freeze and to be able to compress the lesion to remove the blood, although liquid nitrogen can also be used.

- Moisten and warm the cryotip in warm water, and apply watersoluble gel to the lesion.
- 2. Make contact with the probe on the hemangioma and *exert firm pressure* to squeeze the blood out of the vascular channels.
- 3. Activate the cryogun, and hold pressure against the lesion throughout the freeze. Begin timing when the ice ball becomes visible. For larger lesions, freeze for 1½ minutes or until the ice ball extends out 3 mm. Allow 5 to 7 minutes for thawing, and then repeat the freeze.

#### Skin Verrucae

Liquid nitrogen spray is the most effective and most rapid. Use a freeze/thaw/refreeze technique and obtain a 1- to 2-mm margin for each treated wart. Repeat the treatments every 1 to 3 weeks based on response. Débride any necrotic tissue before the next freeze.

**Figure 14-20** Full-thickness destructive freeze of vascular lesion. Pressure is applied to the tip to express as much blood as possible.

#### Seborrheic Keratoses

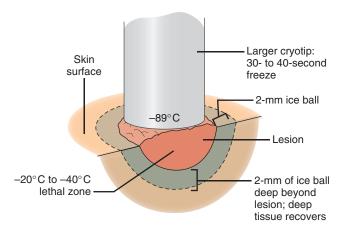

Seborrheic keratoses are usually quite superficial. However, they frequently demonstrate a thick raised component. They are quickly treated using liquid nitrogen because débridement, anesthesia, and soaking are usually not required. For nitrous oxide, the raised lesions may need to be débrided or hydrated before cryosurgery can be effective. Because the procedure takes longer, anesthesia using 1% lidocaine may be needed with nitrous oxide, especially in larger lesions. A 2-mm ice ball margin is sufficient for treatment (Fig. 14-21).

## Cryotherapy for Cervical Intraepithelial Neoplasia

See Chapter 138, Cryotherapy of the Cervix.

## **COMPLICATIONS AND SHORTCOMINGS**

- Pigment cells and hair cells may be destroyed by cryosurgery.
- Hypertrophic scars, verrucae, and vascular lesions are quite resistant to treatment and may recur, requiring several treatments.
- Areas of poor circulation may be susceptible to prolonged ulcer formation, especially in elderly diabetic patients (e.g., anterior tibial compartment).

**Figure 14-21** Nitrous oxide partial-thickness freeze used for removal of superficial lesions (e.g., seborrheic keratoses). Cryotip should cover or nearly cover entire lesion to limit depth of freeze. Halo thaw time should be approximately 30 to 45 seconds for all methods.

- Tissue pathology documentation and verification of adequate destruction of malignant lesions is not possible with cryosurgery. Pretreatment biopsy is recommended for all lesions suspect for malignancy. A presumed "benign lesion" may indeed be malignant and thus insufficiently treated with cryosurgery alone. So, if there is doubt concerning a possible melanoma or squamous cell cancer, biopsy is recommended first.
- Cryosurgery in the periorbital area may cause excessive swelling, in
  which the eyelid may be shut for several hours or days. However,
  cryosurgery of small, well-localized lesions on the eyelids is usually
  well tolerated. Be conservative on the freeze time until the individual patient's reaction is documented.
- Peripheral neuropathy (the ulnar nerve at the elbow or peripheral nerves on the lateral aspect of the digits) can result when areas adjacent to nerves are frozen. The nerve sheath is cryoresistant, but the nerve tissue is more susceptible to damage. This side effect can be minimized (if using a closed nitrous oxide or carbon dioxide system) by pulling the skin outward and away from the nerve, once good contact is achieved. If the nerve is affected, recovery occurs within 4 to 6 weeks, although 3 to 6 months may occasionally be required. Sensory nerves are more likely to be affected.
- In general, the skin of infants and the elderly, as well as previously damaged skin, is more susceptible to necrosis and blistering than normal skin. Thin skin can be a result of sun exposure, radiation, and chronic topical steroid application. Reduce freeze times until the reaction of a damaged area is known.
- One of the most common lesions treated with cryosurgery is active keratosis. Should any lesion not totally resolve after treatment, especially if it persists after a second cryosurgery session, it should be sampled. These resistant lesions are frequently found to be squamous cell carcinomas.

## POSTPROCEDURE PATIENT EDUCATION

The patient should be informed of the anticipated healing time and results, as well as the need to call the office should there be an overreaction to freezing. If the blister enlarges more than 5 to 6 mm beyond the lesion, it might be best to open it. The basic instructions would be the same as those given with a second-degree burn. If the skin from the blister peels off, use moist healing techniques. Document that the patient was told of permanent pigment changes, possible nerve involvement, and hair loss. Placing a copy of the handout that was given to the patient in the chart provides excellent medical-legal documentation as well as an excellent medical reference for staff and physician alike. See patient education and patient consent forms available online.

#### **COMMON ERRORS**

The most common errors encountered in cryosurgery relate to undertreating the lesion. This usually occurs because of failure to ensure adequate ice ball formation in and around the lesion. Lack of consistent contact of the freezing tip with the lesion or failure to follow proper technique when using the liquid nitrogen spray leads to clinical failure. Inadequate freeze often occurs in plantar warts because of the insulating effect of keratin. Unless this is removed before treatment, cryosurgery is less likely to be effective. Selection of cryogen agent is important especially when treating malignancy. A canister refrigerant cannot achieve cold enough temperatures to treat malignancy effectively. Conversely, overfreezing lesions may lead to local side effects, especially hypopigmentation.

### **CPT/BILLING CODES**

Cryosurgery is billed out as "destruction of lesions." Certain areas require specific codes.

## Destruction (Cryocautery, Electrocautery, Laser, Chemical, or Curettement)

#### Benign Lesions

(Site and size not needed, except for locations noted following)

- 11200 Skin tags, 1 to 15 lesions
- 11201 Skin tags, each additional 10 lesions or portion thereof
- 17000 Destruction of *premalignant* lesions (actinic keratosis); first
- 17003 Second through 14 premalignant lesions, each (used in conjunction with 17000) (charge for each additional lesion treated)
- 17004 Destruction of *premalignant* lesions, 15 or more lesions (do not report 17004 in conjunction with 17000-17003)
- 17110 Benign other than skin tags 15 or less
- 17110 Destruction of benign lesions other than skin tags or cutaneous vascular lesions up to 14 lesions
- 30117 Destruction of intranasal lesion
- 46614 Anal, with anoscopy
- 46916 Anal (perianal), benign lesion, simple destruction, cryo
- 46924 Anal (perianal), benign lesion, extensive destruction
- 46934 Anal, internal hemorrhoid
- 46937 Anal, benign rectal tumor
- 54056 Genitals (male), penis, cryotherapy, simple destruction
- 54065 Genitals (male), penis, cryotherapy, extensive destruction
- 56501 Genitals (female), perineum, simple destruction
- 56501 Genitals (female), vulva/introitus, simple destruction
- 56515 Genitals (female), vulva/introitus, extensive destruction
- 57061 Genitals (female), vagina, simple destruction
- 57065 Genitals (female), vagina, extensive destruction
- 57511 Cervix
- 67850 Eyelid, lid margin
- 68135 Eyelid, conjunctiva

## Malignant Lesions

See codes 17260 to 17286 as follows.

**NOTE:** All of these codes have a 10-day global fee surgical period. Destruction by any method, with or without curettement, includes local anesthesia and ablation, and usually does not require closure. Sizes listed describe *lesion* diameter, not the width of the skin area destroyed.

- 17260 Trunk, arm, or leg (TAL): <0.5 cm
- 17261 TAL: 0.6-1.0 cm
- 17262 TAL: 1.1-2.0 cm
- 17263 TAL: 2.1–3.0 cm
- 17264 TAL: 3.1-4.0 cm
- 17266 TAL: >4.0 cm
- 17270 Scalp, neck, hand, foot, or genitalia (SNHFG): <0.5 cm
- 17271 SNHFG: 0.6–1.0 cm
- 17272 SNHFG: 1.1-2.0 cm
- 17273 SNHFG: 2.1-3.0 cm
- 17274 SNHFG: 3.1-4.0 cm
- 17276 SNHFG: >4.0 cm
- 17280 Face, eyelid, ear, nose, lip, or mucous membrane (Face mm): <0.5 cm
- 17281 Face mm: 0.6-1.0 cm
- 17282 Face mm: 1.1–2.0 cm
- 17283 Face mm: 2.1–3.0 cm
- 17284 Face mm: 3.1–4.0 cm
- 17286 Face mm: >4.0 cm

## **ICD-9-CM DIAGNOSTIC CODES**

See ICD-9-CM Code Book under "neoplasm, skin." Then identify anatomic site and whether lesion is benign, malignant (primary or secondary), carcinoma in situ, or uncertain.

## **PATIENT EDUCATION GUIDES**

## **DERMOSCOPY**

Ashfaq A. Marghoob • Azadeh Esmaeili • Alon Scope

Skin cancer, the most common malignancy in the United States, is associated with significant morbidity and mortality. Fortunately, early detection of skin cancer, through visual examination of the entire cutaneous surface, can have a positive impact on patient outcomes. Because dermoscopy can assist clinicians in correctly identifying cutaneous malignancies, it has been well received by physicians engaged in skin cancer screening efforts.

Dermoscopy is a technique that requires the use of hand-held magnification devices known as dermoscopes (or dermatoscopes). These instruments illuminate the skin and, by exploiting the optical properties of the skin, allow the physician to visualize subsurface colors and structures. Dermoscopes are designed to reduce the amount of light reflected off the skin surface, thereby allowing clinicians to appreciate the appearance of the subsurface anatomic structures of the epidermis and papillary dermis that are otherwise not discernible to the unaided eye. Two types of dermoscopes are available, one using standard light-emitting diode (LED) illumination (i.e., nonpolarized dermoscopy) and the other using cross-polarized light (polarized dermoscopy; Fig. 15-1). To reduce skin surface light reflection, nonpolarized dermoscopy requires direct skin contact in the presence of a liquid interface (e.g., mineral oil or alcohol) between the dermoscope and the skin. Polarized dermoscopy, however, does not require an immersion liquid because one of the inherent properties of cross-polarized light is to filter out light reflected from the skin surface, allowing only light reflected from deeper layers of the skin to reach the observer's retina. Polarized and nonpolarized dermoscopy provide complementary information. For example, polarized dermoscopy is the preferred method for visualizing blood vessels because it does not require direct skin contact. The ability to see dermoscopic structures without direct skin contact eliminates the effect of contact pressure-induced blanching of the blood vessel. Nonpolarized dermoscopy, on the other hand, is better for visualizing structures within the superficial layers of the epidermis, such as milia cysts, which are important structures that enable observers to correctly identify seborreic keratoses. With these scopes, clinicians can now appreciate morphologic alterations in skin lesions as dermoscopic structures of different shapes and colors (Table 15-1).

Because most dermoscopic colors and structures have been correlated with histopathologic findings, dermoscopy can be considered a form of bedside in vivo gross tissue inspection that can help to predict tissue pathology.

The overall clinical diagnostic accuracy for malignant melanoma (MM), without the added benefit of dermoscopy, for experienced dermatologists is only about 60%. Dermoscopy enhances the diagnostic accuracy for MM and helps triage those lesions requiring a biopsy. In a large meta-analysis of dermoscopy studies, Bafounta and colleagues revealed that dermoscopy significantly increased diagnostic accuracy (by 49%) compared with unaided examination, with mean sensitivity increasing by 19% and mean specificity by 6%. The increase in specificity with dermoscopy translates into a reduction in the excision of benign lesions. This is consistent with a retrospective analysis that showed a significant reduction in the benignmalignant ratio of excised melanocytic lesions from 18:1 in the predermoscopy era to 4:1 after dermoscopy was implemented by trained clinicians. The benefit of using dermoscopy greatly depends on experience, and reliance on dermoscopy by untrained or less experienced examiners was found to be no better than clinical inspection alone. However, studies indicate that participation in short dermoscopy training courses improves confidence and diagnostic performance of nonexperts when evaluating lesions by dermoscopy. The benefits provided by the use of dermoscopy are presented in Box 15-1.

## EVALUATION TECHNIQUE: TWO-STEP DERMOSCOPY ALGORITHM

The two-step dermoscopy algorithm forms the foundation for the dermoscopic evaluation of skin lesions (Fig. 15-2).

The first step in performing dermoscopy requires that the observer classify the lesion under investigation as either a growth of melanocytic or nonmelanocytic origin. On nonglabrous skin, the presence of a pigment network, aggregated globules, streaks, or homogeneous blue pigmentation identifies the lesion as melanocytic (Figs. 15-3 through

**Figure 15-1** Physician examining a pigmented skin lesion under contact nonpolarized dermoscopy (**A**) and noncontact polarized dermoscopy (**B**).

TABLE 15-1 Dermoscopic Structures and Their Histopathologic Correlations			
Dermoscopic Structures	Definition	Histopathologic Correlation	
Pigment network (reticulation)	Gridlike network consisting of pigmented "lines" and hypopigmented "holes."	Melanin in keratinocytes or melanocytes along the epidermal rete ridges.	
Pseudonetwork	In facial lesions, diffuse pigmentation interrupted by nonpigmented follicular openings, appearing similar to a network.	Pigment in the epidermis or dermis interrupted by follicular and adnexal openings of the face.	
Structureless (homogeneous) areas	Areas devoid of dermoscopic structures and without regression. These areas can be pigmented or nonpigmented. If the area is uniformly dark, it is referred to as a "blotch" (see below).	Lack of melanin or presence of melanin in all layers of the skin.	
Dots	Small, round structures less than 0.1 mm in diameter that may be black, brown, gray, or bluish.	Aggregates of melanocytes or melanin granules. Black dots represent pigment in the upper epidermis or stratum corneum. Brown dots represent pigment at the dermoepidermal junction. Gray-blue dots represent pigment in the papillary dermis.	
Peppering	Tiny, blue-gray granules.	Melanin deposited as intracellular (mostly within melanophages) or extracellular particles in the upper dermis	
Globules	Round to oval structures that may be brown, black, or red with diameters greater than 0.1 mm.	Nests of melanocytes in the dermis and dermal–epidermal junction.	
Streaks (pseudopods, radial streaming)	Radially arranged projections of dark pigment (brown to black) at the periphery of the lesion.	Confluent junctional nests of melanocytes.	
Blotches	Dark brown to black, usually homogeneous areas of pigment that obscure underlying structures.	Aggregates of melanin in the stratum corneum, epidermis, and upper dermis.	
Regression areas	White, scarlike depigmentation (lighter than the surrounding skin, shiny white under polarized dermoscopy) often combined with or adjacent to blue-gray areas or peppering.	Scarlike changes: thickened fibrotic papillary dermis, dilated blood vessels, sparse lymphocytic infiltrates, and variable numbers of melanophages.	
Blue-white veil	Irregular, confluent blue pigmentation with an overlying white "ground-glass" haze.	Aggregation of heavily pigmented cells (usually melanoma cells or melanophages) with compact orthokeratosis of the stratum corneum and acanthosis (thickened epidermis).	
Vascular pattern	See Table 15-5 for vascular terminology.	Tumor neoangiogenesis and dilated blood vessels in the papillary dermis ("vascular blush").	
Milia-like cysts	Round whitish or yellowish structures that shine brightly (like "stars in the sky") under nonpolarized dermoscopy.	Horn pseudocysts.	
Comedo-like openings	"Blackhead"-like plugs on the surface of the lesion.	Concave clefts in the surface of the epidermis, often filled with keratin.	
Fingerprint-like structures	Thin, light brown, parallel running lines.	Probably represent thin, elongated, pigmented epidermal rete ridges.	
Ridges and fissures	Cerebriform surface resulting in gyri (ridges) and sulci (fissures). Confluence of adjacent comedo-like openings will create a fissure.	Wedge-shaped clefts of the surface of the epidermis, often filled with keratin (fissures).	
"Moth-eaten" border Leaf-like areas	Concave invaginations of the lesion border.  Brown to gray-blue, discrete bulbous structures resembling a leaf pattern.	Not available.  Large, complex nodules of pigmented basal cell carcinoma in the upper dermis.	
Spoke-wheel-like structures	Well-circumscribed brown to gray-blue-brown radial projections meeting at a darker brown central hub.	Nests of basal cell carcinoma radiating from the follicular epithelium.	
Large blue-gray ovoid nests Multiple blue-gray globules	Large, well-circumscribed areas, larger than globules. Round well-circumscribed structures that, in the absence of a pigment network, suggest basal-cell carcinoma.	Large nests of basal cell tumor in the dermis. Small nests of basal cell tumor in the dermis.	
Lacunae Parallel patterns	Red, maroon, or black lagoons.  On acral areas, parallel rows of pigmentation following the furrows (nevi) or ridges (melanoma) of the dermoglyphics.	Dilated vascular spaces.  Pigmented melanocytes in the furrows (crista limitans) or ridges  (crista intermedia) of acral skin.	

## Box 15-1. Benefits of Dermoscopy

Allows the observer to formulate a logical differential diagnosis

Differentiates melanocytic from nonmelanocytic skin lesions Differentiates benign from malignant skin lesions

Provides earlier diagnosis of melanoma

Improves diagnostic accuracy

Increases the confidence in diagnosis

Avoids unnecessary biopsies

Helps isolate suspicious foci within a large lesion

Helps define lesion borders for presurgical margin mapping Aids in monitoring patients with multiple nevi

Helps reassure patients

15-6). In addition, a pseudonetwork pattern can be seen in melanocytic lesions on facial skin (Fig. 15-7). On the other hand, melanocytic lesions on the palms and soles are recognized primarily by the presence of a parallel pigment pattern (Fig. 15-8; see Table 15-1). If, however, the lesion does not manifest any of the aforementioned melanocytic criteria, the observer seeks to identify specific criteria that can identify the lesion as a nonmelanocytic lesion (see Fig. 15-2) such as basal cell carcinoma (Figs. 15-9 through 15-11), squamous cell carcinoma (Fig. 15-12), he mangioma (Fig. 15-13), seborrheic keratoses (Figs. 15-14 and 15-15), or dermatofibroma (Fig. 15-16). In addition, a group of lesions exists that is termed "structureless" in that they do not manifest any melanocytic or nonmelanocytic lesion structures. Because it is not uncommon to encounter amelanotic and hypomelanotic MMs that are structureless, all such lesions should be viewed with extreme suspicion, especially if the

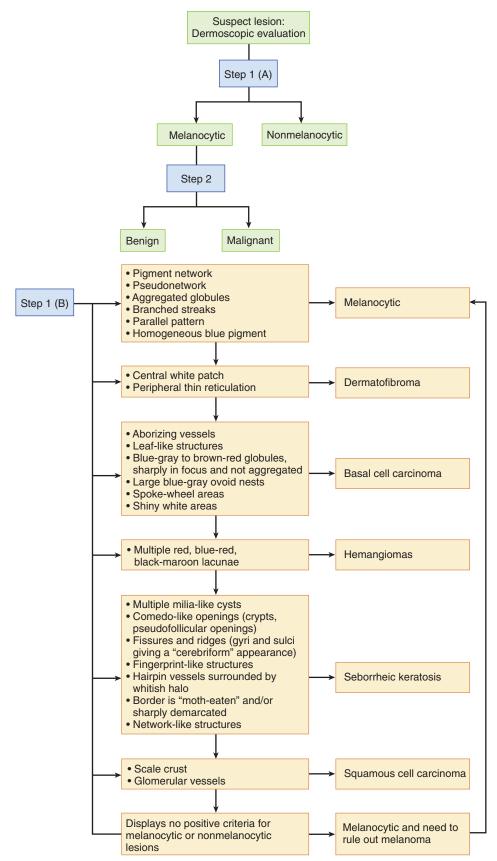

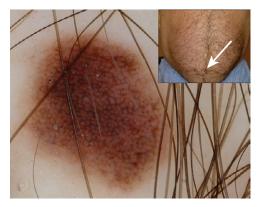

Figure 15-2 The two-step algorithm for the evaluation of the pigmented lesions. In the first step, the observer must decide whether the lesion is of melanocytic or nonmelanocytic origin (Step I [A]), using a stepwise evaluation of dermoscopic features (Step I [B]). In the second step, the observer differentiates between benign melanocytic nevi and melanoma using pattern analysis or one of the score-based algorithms mentioned in the text (e.g., ABCD rule, Menzies method, seven-point checklist).

**Figure 15-3** This abdominal pigmented lesion is larger and darker than the patient's other moles (*inset*, *arrow*) and thus can be considered an "ugly duckling" that requires close-up examination. On dermoscopy, there is a pigmented network, and thus the lesion is melanocytic in origin. The lesion displays a regular network thinning out at the periphery, which is a benign nevus pattern.

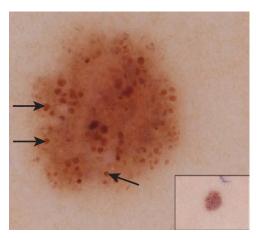

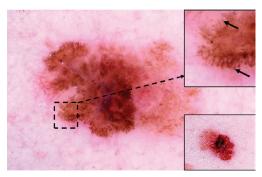

Figure 15-4 Pigmented lesion featuring aggregated globules (arrows) with an overall symmetric distribution, which is a benign nevus pattern.

**Figure 15-5** This lesion is clinically suspect by the ABCD criteria for melanoma (*inset*). On dermoscopy, the lesion does not display any of the benign nevus patterns and has peripheral streaks shaped like pseudopods (*dotted box and corresponding inset*). The streaks are focally placed; their presence indicates that the lesion is melanocytic and raises concern for melanoma. This was a 0.4-mm melanoma.

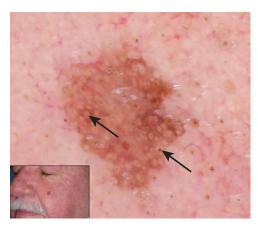

**Figure 15-6** Blue nevus showing homogeneous steel-blue pigmentation (one of the benign nevus patterns: the homogeneous pattern).

lesion manifests linear irregular or dotted blood vessels, both commonly seen in MM (Fig. 15-17).

The second step in the two-step dermoscopy algorithm pertains only to lesions that are deemed to be of melanocytic origin, which include both lesions with melanocytic-specific features (Table 15-2) and those that are structureless. The objective during this second-tier evaluation process is to differentiate benign nevi from MM. Toward this goal, a number of algorithms have been created. Novices in dermoscopy may find one of the score-based algorithms useful in assessing melanocytic lesions (Box 15-2, Tables 15-3 and 15-4, and Figs. 15-18 and 15-19). However, once experience in dermoscopy is attained, most dermoscopists rely on pattern analysis to differentiate between nevi and MM.

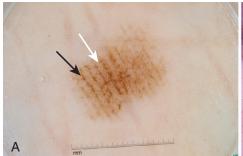

Although pattern analysis requires experience; a *simplified form* of pattern analysis can be taught to novices in dermoscopy (Box 15-3). Fortunately, most benign nevi tend to manifest one of nine benign global patterns, all of which are characterized by symmetry of dermoscopic colors and structures. Hence, knowing these benign global patterns can prevent the excision of many atypical moles, most of which will reveal one of these benign patterns. Any lesion that deviates from one of these global benign patterns needs to be viewed with caution.

The nine benign global dermoscopic patterns include (1) diffuse reticular network, (2) patchy reticular network, (3) peripheral reticular network with central hypopigmentation, (4) peripheral reticular network with central hyperpigmentation, (5) peripheral reticular network with central globules, (6) globular pattern, (7) peripheral globules with central reticular network or starburst, (8) homogeneous pattern, and (9) symmetric multicomponent pattern (Figs. 15-20 and 15-21; see Box 15-3). Based on the aforementioned

**Figure 15-7** Pigmented lesion on the face featuring a pseudonetwork pattern, produced by pigmentation surrounding adnexal openings such as hair follicles (*arrows*).

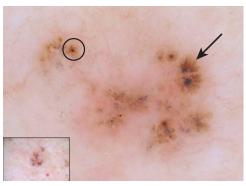

**Figure 15-8 A,** Acral nevus exhibiting a parallel furrow pattern, where pigmentation is seen in the furrows (black arrow) but does not involve the ridges (white arrow). **B,** Acral melanoma displaying the opposite pattern, with the pigmentation on the ridges (white arrow) but not in the furrows (black arrow). To help distinguish ridges from furrows, one can look for the sweat gland openings, which are always located on the ridges (white arrowheads).

**Figure 15-9** Pigmented nodular basal cell carcinoma featuring arborizing telangiectases (*black arrow, top*), ovoid nest (*black arrow, bottom*), and multiple blue-gray globules (*white arrow*).

**Figure 15-10** Pigmented basal cell carcinoma showing spoke-wheel-like structures (*circle*) and leaflike areas (*arrow*). Both of these structures are 100% specific for the diagnosis of basal cell carcinoma.

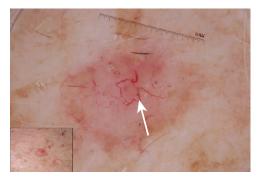

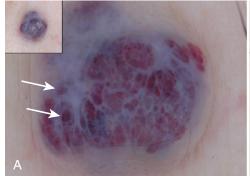

Figure 15-11 Nonpigmented basal cell carcinoma featuring arborizing telangiectases (arrow).

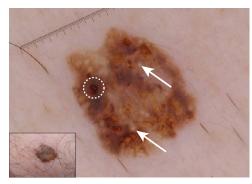

Figure 15-12 This keratotic lesion (inset) reveals clusters of glomeruloid vessels (arrows), suggestive of the diagnosis of squamous cell carcinoma.

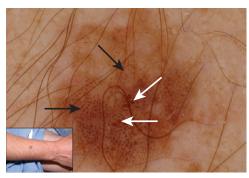

**Figure** 15-13 A, Hemangioma showing multiple lacunae of variable size, with a spectrum of colors from red to blue (arrows). B, Cherry hemangioma showing multiple bright to dark red lacunae (arrows).

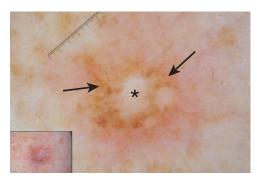

**Figure 15-14** Seborrheic keratosis featuring sharp borders, comedolike openings (dotted circle), and multiple milia-like cysts (arrows).

**Figure 15-15** Seborrheic keratosis featuring a cerebriform pattern. The ridges (gyri, black arrows) are the raised portion of the lesion, and the fissures (sulci, white arrows) are crypts filled with keratin.

**Figure 15-16** Dermatofibroma featuring a central depigmented scarlike area (asterisk) with surrounding peripheral network (arrows).

**Figure 15-17** This nodule is amelanotic and lacks specific melanocytic or nonmelanocytic criteria of the two-step algorithm of dermoscopy. Thus, by default, one needs to consider melanoma in the differential diagnosis. Indeed, this lesion features atypical hairpin vessels (*arrows*), a clue to the correct diagnosis. This proved to be a nodular melanoma.

TABLE 15-2 Dermoscopic Criteria for Melanocytic Lesions			
Dermoscopic Criterion	Definition		
Benign Nevi			
Reticular pattern	Pigment network of relative uniform thickness and color with holes of relative uniform size. Small brown or black dots can often be seen overlying the network or within the center of the lesion.		
Globular pattern (includes cobblestone pattern)	Numerous, round-to-oval to angulated structures with various shades of brown. The globules are of uniform size, shape, and color and are distributed symmetrically.		
Homogeneous pattern	Diffuse brown, gray-blue to blue-white pigmentation.		
Starburst pattern	Finger-like projections seen at the edge of the lesion. The pigmented streaks are distributed symmetrically along the entire perimeter of the lesion in a radial arrangement.		
Pseudonetwork pattern (face)	Pigmented lesion on facial skin with interruption of the pigment due to the presence of follicular and adnexal openings. This results in a network-like appearance.		
Parallel furrow pattern (palms & soles)	Pigment located along the furrows of the palms and soles.		
Melanoma			
Multicomponent pattern	Presence of three or more of the aforementioned patterns.		
Atypical pigment network	Black, brown, or gray network with irregular-sized holes and thickened network lines. The network is often broken up, creating branched streaklike structures within the lesion.		
Irregular dots/globules	Black, brown, round-to-oval structures distributed asymmetrically, not overlying the lines of a network, and often located toward the periphery of the lesion.		
Irregular streaks	Finger-like projections seen at the edge of the lesion but distributed asymmetrically and focally along the perimeter of the melanoma.		
Blotches	Black, brown, blue, or gray structureless areas distributed asymmetrically and not involving the entire lesion in a homogeneous manner.		
Vascular structures	Dotted vessels, linear irregular vessels, thick and tortuous vessels, or erythema.		
Annular-granular structures and pseudonetwork (Face) Parallel-ridge pattern (palms/soles)	Multiple blue-gray dots surrounding the follicular ostia, creating an annular-granular pattern. Once the pigment becomes confluent a pseudonetwork-like pattern emerges, which creates rhomboidal-like structures. Pigmentation aligned along the ridges on the palms and soles. This openings of the sweat ducts are located on the		
raraner mage pattern (pairits/30les)	ridegs.		

## Box 15-2. Menzies Method

## Negative Features (Neither Feature Found)

Symmetry of pattern (Assess only the colors and structures within the lesion. The symmetry/asymmetry of the contour/silhouette of the lesion is not a factor in this evaluation method.)

Presence of only a single color

## Positive Features (At Least One Feature Found)

Blue-white veil Pseudopods Scarlike depigmentation Multiple (5–6) colors Broadened network Multiple brown dots

Radial streaming

Peripheral black dots/globules

Multiple blue-gray dots ("peppering")

For melanoma to be diagnosed, the lesion must have neither of the two morphologic negative features and at least one of the nine positive features.

## TABLE 15-3 ABCD Rule of Dermoscopy

Components of the ABCD Rule	Description	Score
Asymmetry	In 0,1, or 2 perpendicular axes; assess not only contour, but also colors and structure	0–2
Border	Abrupt cut-off of pigment pattern at the periphery in 0 to 8 segments	0–8
Colors	Presence of up to 6 colors (white, red, light brown, dark brown, blue-gray, black)	1–6
Dermoscopic structures	Presence of network, structureless (homogeneous) areas, branched streaks, dots and globules	I <i>-</i> 5

#### **Calculation of Total Dermoscopy Score**

A distinction between benign and malignant melanocytic lesions can often be made using the following formula: [(A score × 1.3) + (B score × 0.1) + (C score × 0.5) + (D score × 0.5)].

Interpretation of total score: <4.75, benign nevi; 4.75–5.45, suspicious for melanoma; >5.45, melanoma.

## TABLE 15-4 Seven-Point Checklist

Criteria	Score
Major Criteria Atypical pigment network Blue-white veil Atypical vascular pattern	2 2 2
Minor Criteria Irregular streaks Irregular dots/globules Irregular blotches Regression structures	 
Seven-Point Total Score Nonmelanoma Melanoma	<3 ≥3

By simple addition of the individual scores, one can differentiate between many benign nevi and melanoma. A minimum total score of 3 is required for the diagnosis of melanoma, whereas a total score of less than 3 indicative of a benign nevus.

## Box 15-3. Revised Pattern Analysis

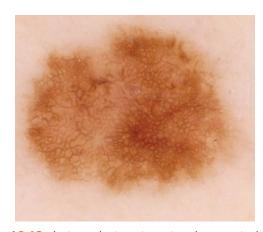

## Nine Benign Nevus-Specific Patterns (All Exhibit Symmetry of Structure, Color, and Pattern)

- 1. Diffuse reticular network
- 2. Patchy reticular network
- 3. Peripheral reticular network with central hypopigmentation
- 4. Peripheral reticular network with central hyperpigmentation
- 5. Peripheral reticular network with central globules
- 6. Globular pattern
- 7. Peripheral globules with central reticular network or starburst
- 8. Homogeneous pattern
- 9. Symmetric multicomponent pattern

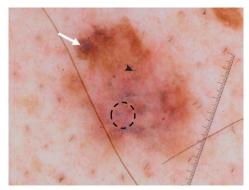

## Nine Melanoma-Specific Structures

- 1. Atypical network
- 2. Streaks
- 3. Atypical dots or globules
- 4. Negative pigment network
- 5. Off-center pigmented blotch
- 6. Blue-white veil overlying flat areas
- 7. Blue-white veil overlying raised areas
- 8. Atypical vascular structures
- 9. Brown peripheral structureless area

Any lesion that does not conform to one of the benign nevus patterns or exhibits at least one of the melanoma-specific structures listed here should raise suspicion for melanoma. Thus, most melanomas will display asymmetry of structure, color, and pattern.

**Figure 15-18** Lesion evaluation using various dermoscopic algorithms. The seven-point checklist of dermoscopy identifies only atypical network (two points). The total score is 2, denoting a benign lesion (i.e., nevus). Evaluation using the Menzies method also leads to the conclusion that this is a nevus because the lesion shows a single color and overall symmetry of structure and pattern. Lesion evaluation using the ABCD rule indicates a total score of 3.3 (A = 1.3 for asymmetry in one axis [comparing right and left halves of the lesion], B = 0 because the lesion gradually fades into the periphery, C = 1 for the color brown, and D = 1 for the presence of network). This score is within the benign range of the ABCD method.

**Figure 15-19** Lesion evaluation using various dermoscopic algorithms. By the seven-point checklist of dermoscopy the lesion displays an irregular blotch (arrow, one point), irregular dots/globules (arrowhead, one point), and regression structures with bluish peppering ( $dotted\ circle$ , one point). The total score is 3, denoting a melanoma. Evaluating the same lesion by the Menzies method also leads to the same conclusion because the lesion has more than one color and has asymmetry of structure and pattern. It also has blue-gray peppering ( $dotted\ circle$ ). Thus, this lesion is a melanoma. Lesion evaluation using the ABCD indicates a total score of 6.6 (A = 2.6 for two-axis asymmetry, B = 0 because the lesion fades gradually into the periphery, C = 2 for the presence of four colors [light and dark brown, blue-gray, and red], and D = 2 for the presence of network, structureless areas, and dots and globules). The lesion has dermoscopic features consistent with melanoma.

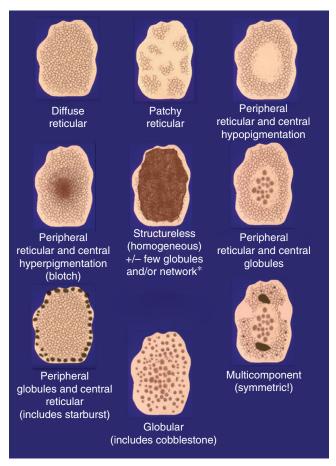

Figure 15-20 The nine benign global dermoscopic patterns of nevi. \*"Structureless" refers to a hyper- or hypopigmented blotch.

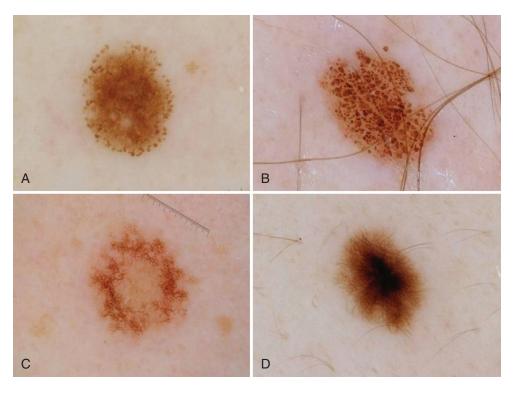

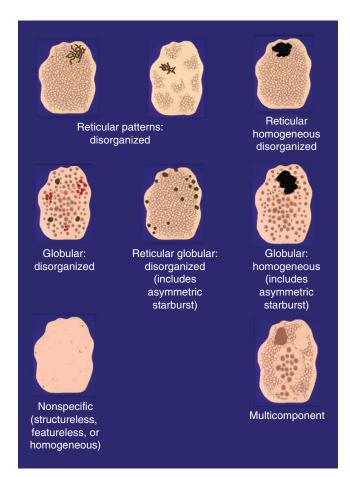

Figure 15-21 Examples of benign global dermoscopic patterns. A, Peripheral globules and central reticular. B, Globular pattern. This variant is called the "cobblestone" pattern because the globules are large and angulated, arranged almost back to back. C, Peripheral reticular and central hypopigmentation. D, Peripheral reticular and central hyperpigmentation.

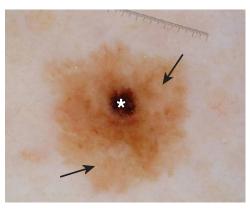

**Figure 15-22** Global dermoscopic patterns commonly seen in melanoma. Specific (local) dermoscopic structures that should raise suspicion for malignancy include atypical network; streaks; atypical dots or globules; negative pigment network; off-center pigmented blotch; blue-white veil overlying flat areas; blue-white veil overlying raised areas; atypical vascular structures; and brown peripheral structureless area.

features common to benign nevi, it stands to reason that most melanocytic nevi will be symmetric, uniform, display less than three colors, and have an organized architecture.

In contrast, MM often exhibits a pattern that deviates from the aforementioned benign patterns, manifests asymmetry of dermoscopic colors and structures, and displays a disordered dermoscopic architecture. Most MMs also contain at least one of the following nine specific dermoscopic structures: (1) atypical network, (2) peripheral streaks, (3) atypical dots or globules, (4) negative pigment network, (5) off-center pigmented blotch, (6) blue-white veil overlying flat areas, (7) blue-white veil overlying raised areas, (8) atypical vascular structures, and (9) brown peripheral structureless area (Figs. 15-22 and 15-23; see Box 15-3).

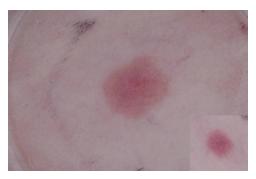

Although most MMs display at least some degree of asymmetry of pattern, color, and structure, there exists a subset of early MMs that are structureless. Fortunately, most of these early MMs can be correctly identified based on observing their growth dynamics or by visualizing the presence of an increased vasculature.

Neoangiogenesis, resulting in an increased blood volume, is required for MM survival and growth. These neoangiogenic blood vessels can often be visualized under dermoscopy, and their presence can help correctly identify many MMs. Studies have shown that the specific morphology of the blood vessels observed under dermoscopy is correlated to specific tumors (Table 15-5). The most common vessel morphologies exhibited by MM are linear-irregular and dotted vessels (Fig. 15-24). Hence, the presence of such vessels in

**Figure 15-23** Although this lesion has symmetry of structure and pattern, it does not conform to one of the nine benign patterns. In addition, it has peripheral brown structureless areas (arrows) and an atypical network in the center (asterisk). This was an in situ melanoma.

TABLE 15-5 Vascular Structures with Associated Tumors		
Primary Vessel Morphology	Disease Entity	
Arborizing vessels Comma vessels	Basal cell carcinoma Intradermal nevus Congenital melanocytic nevus	
Corkscrew vessels	Nodular melanoma Cutaneous melanoma metastasis Desmoplastic melanoma	
Dotted and globular vessels	Melanoma Spitz nevus Dysplastic nevus Squamous cell carcinoma	
Glomerular vessels Hairpin vessels	Squamous cell carcinoma Keratoacanthoma Melanoma Irritated seborrheic keratosis Squamous cell carcinoma Spitz nevus	
Linear irregular vessels	Melanoma Spitz nevus	
Milky red area/globule Polymorphous vessels	Melanoma Melanoma	

**Figure 15-24** Invasive melanoma (0.45 mm in Breslow depth) lacking any pigmented dermoscopic features, and showing only dotted vessels throughout the lesion.

Figure 15-25 Side-by side comparison of sequential dermoscopic images at baseline (A) and 9-month follow-up (B). No dermoscopic changes are seen on follow-up examination; therefore, the lesion is considered biologically benign.

a hypopigmented or amelanotic lesion is an important clue to the diagnosis of MM.

Malignancies, being biologically active, are growing lesions, whereas benign nevi are usually in a state of senescence. This fact can be used by clinicians to help isolate early MMs that have not yet developed any of the MM-specific dermoscopic structures mentioned previously (i.e., structureless MM) from among many benign nevi. The acquisition of sequential dermoscopic images provides physicians with the ability to monitor lesions for change. This ability to compare baseline and follow-up dermoscopic images of the same lesion over time increases the specificity of MM diagnosis while at the same time maintaining a high sensitivity, which

translates into the appropriate removal of MMs with a concomitant reduction in the unnecessary removal of benign lesions (Figs. 15-25 and 15-26).

Sequential imaging is usually restricted to patients with multiple atypical nevi because it is often more practical to simply remove a single atypical mole on a patient with few to no additional nevi than it is to follow them. For individuals possessing many nevi, the removal of all of their atypical moles would be impractical. In such patients, sequential dermoscopic imaging appears to be a reasonable management strategy. The principle is that if a lesion is found to be stable, the patient can be reassured that the lesion is biologically indolent at that moment in time and thus can be followed routinely.

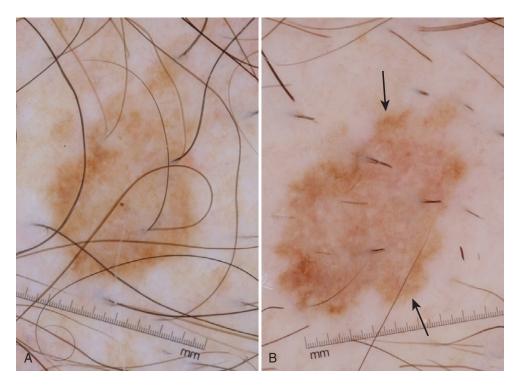

Figure 15-26 Dermoscopic follow-up using side-by side comparison of sequential dermoscopic images at baseline (A) and 4-month follow-up (B). At follow-up, radial growth of the lesion can be appreciated (B, arrows). This lesion, which otherwise does not display melanoma-specific dermoscopic features, proved to be an invasive melanoma 0.3 mm in Breslow depth.

#### **SHORT-TERM MOLE MONITORING**

The most timely method, short of performing a biopsy, for correctly segregating benign lesions from MM is by sequential "short-term" dermoscopic imaging (see Figs. 15-25 and 15-26). Menzies and colleagues (2001) introduced the concept of short-term mole monitoring, which involves sequential reexamination of the same lesion over a 3- to 4-month period. Short-term dermoscopic monitoring is aimed at increasing the specificity of evaluation of equivocal melanocytic lesions. It is used to evaluate melanocytic lesions that lack dermoscopic features of MM, yet appear somewhat atypical to the examiner or have a history of change. In this setting, any morphologic change observed during the 3-month monitoring period warrants an excision. The exceptions to this rule are when one observes an overall increase or decrease in pigmentation without accompanying architectural change or the loss or appearance of milia-like cysts.

The majority (81%) of the lesions followed up in the study by Menzies and colleagues did not change and thus were "spared" from undergoing unnecessary removal. Of the lesions that did reveal change, 11% were found to be MM, all of which proved to be histologically thin tumors, and none revealed any of the MM-specific dermoscopic structures mentioned previously. The specificity for the diagnosis of MM by means of short-term digital monitoring of dermoscopically equivocal lesions was reported to be 83%. In another study, Kittler and associates (2006) followed suspect lesions lacking MM-specific features at baseline for over 8 months. After follow-up of 1.5 to 4.5 months, only 38.2% of the MMs showed specific dermoscopic features for MM. This value increased to 55% after 4.5 to 8.0 months and to 64.9% after more than 8.0 months (Fig. 15-27). The observed changes in MM lesions included asymmetric enlargement, focal changes in pigmentation and structure, regression features, and change in color. Insignificant change observed in lesions after at least 6 months of follow-up included a darker or lighter overall appearance, change in the number or distribution of brown

globules, and disappearance of parts of the pigment network. The conclusion of the study was that MM-specific dermoscopic criteria in structureless MMs become readily apparent as the length of follow-up increases. However, MMs that lack any specific features can in fact be detected by the short-term monitoring process. Thus, MMs lacking MM-specific dermoscopic features can now be detected based on observing their dynamic evolution over time.

#### **DERMOSCOPY IN THE PRIMARY CARE OFFICE**

Approximately 40% of office visits to physicians in the United States are to a primary care physician (PCP), and although most patients with MM had at least one primary care visit in the year before diagnosis, only 20% report receiving a skin cancer examination. Compared with MM detection by the patient or family, MM detected by physicians is more likely to be thinner. PCPs, therefore, are in a unique position to perform skin cancer screening. Studies indicate that training PCPs to screen for MM using dermoscopy leads to increased diagnostic sensitivity without a significant decrease in specificity. Argenziano and colleagues (2006) introduced the three-point checklist for the purpose of improving sensitivity in skin cancer (i.e., MM and basal cell carcinoma) screening by PCPs (Table 15-6 and Figs. 15-28 through 15-30). The three-point checklist was meant to serve as a triage tool to help PCPs in deciding on referrals of pigmented lesions to dermatologists. The study indicated that dermoscopy allows PCPs to perform 25.1% better triage of skin lesions suggestive of skin cancer compared with naked-eye examination alone (P = .002).

In another study among general practitioners, sensitivity for MM diagnosis improved significantly from a clinical baseline pretest of 54% to a post-training dermoscopy diagnosis of 76%. In addition, dermoscopy education created an increased awareness of the clinical appearance of MM among PCPs and improved naked-eye diagnosis of MM. PCPs are encouraged to be formally trained in dermoscopy

Figure 15-27 With long-term follow-up, malignant lesions will increasingly show melanoma-specific dermoscopic structures. This lesion was clinically inconspicuous (A) and dermoscopically showed only a reticular-homogenous pattern (B). However, at 2-year followup (C), the lesion was clinically more suspect, with asymmetry and multiple colors (brown, black, and pink). On dermoscopy at the 2-year follow-up (D), the lesion showed an atypical network (black arrow), multiple dots (dotted circle), and bluish-gray (white arrow) and white scarlike (asterisk) areas suggestive of regression. This was a melanoma 1.8 mm in Breslow depth.

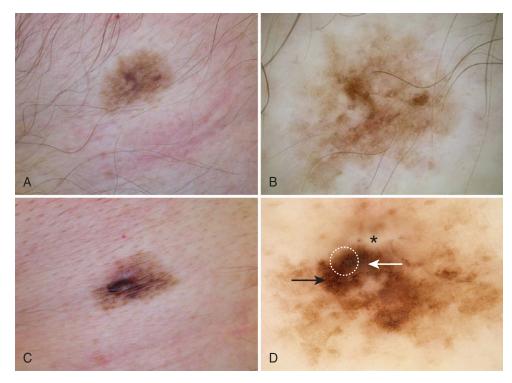

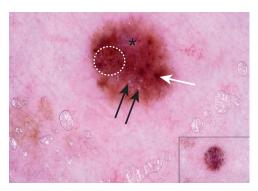

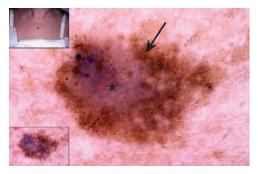

TABLE 15-6 The Three-Point Checklist			
Three-Point Checklist	Definition		
Asymmetry	Asymmetrical distribution of colors and dermoscopic structures.		
Atypical network	Pigmented network with irregular holes and thick line. Streaks are considered part of an atypical network.		
Blue-white structures	Any type of blue or white color, including white scarlike depigmentation, blue-whitish veil and blue pepper-like granules (regression structures).		

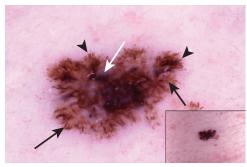

The presence of more than one criterion suggests a suspicious lesion.

**Figure 15-28** This lesion appears clinically symmetric (*inset*). However, dermoscopic evaluation reveals asymmetric distribution of the dermoscopic structures: aggregated globules in the top left quadrant (*dotted circle*), bluewhite structures (*asterisk*), blotches (*white arrow*), and milia-like cysts (*black arrows*). By the three-point checklist the lesion gets a score of 2 for the dermoscopic asymmetry and blue-white structures, denoting a suspect lesion. This lesion was a melanoma 0.5 mm in Breslow depth.

**Figure 15-29** This lesion is an "ugly duckling" that stands out as different on the patient's chest (*top inset*) and shows clinical asymmetry and multiple colors (*bottom inset*). Evaluating this pigmented lesion using the three-point checklist indicates asymmetric distribution of dermoscopic structures, atypical network (*arrow*), and blue-white structures (*asterisk*), for a total score of 3. This lesion was a melanoma 0.5 mm in Breslow depth.

**Figure 15-30** Evaluating this pigmented lesion using the three-point checklist indicates asymmetric distribution of dermoscopic structures, atypical network (*black arrows*), and blue-white structures (*white arrow*). The total score is 3. This lesion was a melanoma 0.3 mm in Breslow depth. Of note, the lesion also displays multiple peripheral streaks (*black arrowheads*), which are considered to be part of the atypical network.

for the clinical assessment of skin tumors, including MM. Australia and New Zealand have successfully implemented a wide network of skin cancer screening by PCPs. In a study assessing New Zealand general practitioners' diagnosis and management of skin cancer, the participating physicians were shown to have a high level of expertise in making the correct diagnosis and in deciding whether or not to biopsy the lesion.

It is important to acknowledge that dermoscopy constitutes only one portion of a thorough history and physical examination. We caution against *solely* relying on the dermoscopic findings while dismissing other clinical cues. For example, a lesion that appears different (either by clinical or dermoscopic examination) relative to its neighboring lesions, known as the *ugly duckling sign*, should raise suspicion in the observer even in the absence of definitive dermoscopic features of MM. The final decision-making process should always evaluate the dermoscopic findings in light of the patient's personal and family history, as well as other clinical parameters of the lesion such as symptoms of pain, bleeding, or itching.

In summary, there is compelling evidence that dermoscopy improves MM diagnosis at an earlier, curable stage while avoiding excessive scarring from removal of benign lesions. As a first-level screening tool, dermoscopy may improve the PCP's ability to detect skin cancer.

### FISHHOOK REMOVAL

John Harlan Haynes III • Terrance S. Hines

Fishhook injuries are relatively common. Confidence in their management is paramount to successful outcomes. The method used to remove a fishhook depends on the anatomic location of the injury and the conditions under which the removal is to take place. The first and least harmful method described is the *string-yank* method, which may be used without anesthesia by anglers on the water. It is best used on the more resilient skin surfaces with underlying bone and muscle. For more embedded hooks, or for hooks in flaccid areas such as the earlobe, the needle cover "barb-sheath" or the pull-through technique may be more applicable. Local anesthesia with 1% lidocaine is well received by the anxious patient in an emergency setting. If the shank has already been clipped by a well-meaning first-aider, a strong needle driver or hemostat may be clamped over the exposed shank tip to facilitate removal.

Occasionally, radiographs may help in determining the type of fishhook and depth of penetration. Before a fishhook is removed, be sure to assess the proximity of the hook to underlying neurovascular or tendon structures and the potential for damage.

#### **INDICATION**

A fishhook embedded in subcutaneous tissue (most commonly, fingers and feet).

#### **CONTRAINDICATIONS**

- Penetration into the eye with scleral perforation (dictates ophthalmology referral)
- Deeply embedded hooks in or near the neck, genitalia, arteries, or the wrist, or possible penetration of gastrointestinal mucosa

#### **ANGLER'S STRING-YANK METHOD**

#### **Equipment**

- Silk suture (0 or larger diameter), umbilical tape, or ordinary string, 2 to 3 feet in length
- 2 to 3 mL of 1% lidocaine in syringe with a 30-gauge needle
- Protective eyewear

#### **Technique**

- Cleanse the skin with an iodinated soap or similar antiseptic solution.
- 2. Inject 2 to 3 mL of 1% local anesthetic around the hook.
- 3. The the midpoint of the string or suture around the curve of the fishhook. Securely wrap the other ends several times around your index and middle finger (Fig. 16-1A).
- 4. Place the involved extremity on a flat surface to provide stabilization. Depress the shank of the hook against the skin with the index finger of your nondominant free hand until it meets resistance. The shaft of the hook is then lifted approximately parallel to the underlying skin by grasping the eye with the thumb and

- middle fingers (Fig. 16-1B). This maneuver disengages the barb from the subcutaneous tissue.
- 5. With the shank depressed and the barb disengaged, grasp the string 12 inches from the hook and firmly and quickly jerk the string, with follow-through, in one forceful move parallel to the shank (Fig. 16-1C). Sudden and forceful pulling on the suture is necessary to prevent failure of the technique. Bystanders should stand clear from the flight path, and protective eyewear should be worn. This method is effective and produces no additional wounds.

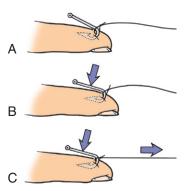

#### **NEEDLE COVER OR "BARB-SHEATH" METHOD**

#### **Equipment**

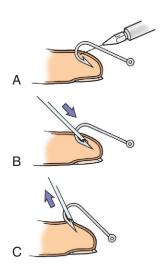

- 0.5 mL lidocaine 1% in a syringe with a 30-gauge needle
- 18-gauge needle
- Protective eyewear

#### **Technique**

- 1. After local anesthesia is injected, introduce the 18-gauge needle through the entrance track along the inside curvature of the hook, parallel to the shank, with the bevel toward the inside of the curve so that the needle opening can engage the barb (Fig. 16-2A and B).
- 2. Advance the hook slightly to dislodge the barb from the tissue. Gently pull and twist the hook so that the barb is firmly sheathed by the lumen of the 18-gauge needle.
- 3. Back the hook and needle out together as a unit (Fig. 16-2C).

**Figure 16-1 A-C**, Angler's string-yank method of fishhook removal. See text for details.

**Figure 16-2** A–C, Removal of a fishhook with anesthetic when the hook is large and not too deep in the skin. See text for details.

#### TRADITIONAL PULL-THROUGH METHOD

#### **Equipment**

- 0.5 mL lidocaine 1% in syringe with a 27-gauge needle
- Wire clipper
- Protective eyewear

#### **Technique**

- 1. Provide local anesthesia over the point of the hook (Fig. 16-3A).
- 2. Force the point through the anesthetized skin (Fig. 16-3B).
- 3. When the barb tip is fully exposed, clip it off (Fig. 16-3C).
- 4. Back the hook out along the direction of entry (Fig. 16-3D).
- 5. Alternatively, if the shank has multiple barbs, clip off the eye of the hook and pull on the sharp end of the hook until the entire hook is removed (Fig. 16-4).

#### **POSTPROCEDURE CARE**

- Explore the wound for possible foreign bodies and débrid it.
- Administer tetanus toxoid if more than 5 years has elapsed since its last administration.
- Prophylactic antibiotic therapy may be considered for persons who
  are immunosuppressed or have diabetes or peripheral vascular
  disease. Prophylactic antibiotics may also be used for deeper or
  contaminated wounds. Coverage should include normal skin flora
  (Staphylococcus aureus and Staphylococcus pyogenes) as well as
  potential water-borne pathogens (Aeromonas species, Edwardsiella

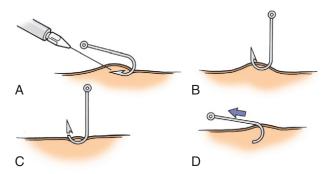

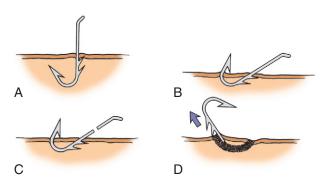

Figure 16-3 A–D, Traditional pull-through method for removing a small fishhook. See text for details.

**Figure 16-4** Removal of a barbed fishhook. **A,** The hook embedded in soft tissue. **B,** Twist the hook forward until the sharp end is visible. **C,** Cut off the eye of the hook. **D,** Pull on the sharp end to remove.

tarda, Erysipelothrix rhusiopathiae, Vibrio vulnificus, and Mycobacterium marinum). Empiric coverage for soft tissue infections after water exposure includes either a first-generation cephalosporin or clindamycin plus levofloxacin plus either metronidazole (sewage-or soil- contaminated wound, not necessary if clindamycin given) or doxycycline (coverage of Vibrio species if seawater exposure).

- Dress the wound with a sterile adhesive bandage and antibiotic ointment.
- Wash the area well with soap and water four to six times a day for 2 days.
- Warn the patient of the possibility of infection.

# FLAPS AND PLASTIES

Dennis LaRavia

Appropriate wound closure after excision is essential in achieving a cosmetically pleasing result. Although many elliptical defects can be repaired with a basic side-to-side closure, large or complex defects may require more advanced techniques. Several techniques for wound closure and scar revision are described in this chapter, including advancement and rotation flaps, V-Y plasties, M-plasties, and the management of dog-ears. The specific flaps and plastic surgery closures described are chosen for their utility, reliability, and predictability of aesthetic result.

#### **INDICATIONS**

- A soft tissue defect is so large that a simple primary closure is not possible. If an elliptical defect may not be pinched together easily between the fingers with minimal tension, a simple side-to-side closure will likely be insufficient.
- There is excessive skin tension with simple closure techniques, and simple closure would yield a poor cosmetic result.
- Surgical skin remodeling techniques, or "plasties," may be indicated when dealing with dog-ears, complex wounds, or other defects that would cause an undesirable scar.

#### **CONTRAINDICATIONS (ALL RELATIVE)**

When performed correctly, the closure techniques described in this chapter generally achieve good results. However, certain risk factors may lead to poor outcomes. Relative contraindications to complex skin closures and flaps include the following:

- Diabetes
- Impaired wound healing history
- Vascular compromise to region
- Keloid or hypertrophic scar formation history
- Prior radiation to region
- Coagulopathy (intrinsic or induced through anticoagulants such as warfarin)
- Wound location on lower extremity, especially the feet (due to slow healing)

Good healing can still be accomplished in most cases if the operator is careful to engage in appropriate communication with the patient to ensure compliance, provides the correct closure technique, and limits platelet aggregation inhibitors (i.e., aspirin, other nonsteroidal anti-inflammatory drugs, and clopidogrel) for 5 days before surgery if possible. If the patient cannot stop these agents, the surgery can still be performed, but the patient should expect more intraoperative bleeding and increased likelihood of postoperative oozing and ecchymoses in the operative area. Patients on warfarin can also have extensive plastic procedures with advanced flaps and closures but should expect slower healing and more prolonged bruising in the operative area. The current recommendation is that warfarin not be stopped for cutaneous surgery because there is a significant risk of stroke. However, depending on the size of the lesion, the procedures described in this chapter can be quite exten-

sive and involved. Consider "bridge therapy" for those patients who need anticoagulation (see Appendix H, Pearls of Practice).

It is particularly important to ask the patient about any history of abnormal scarring, keloids, or poor healing. Certain areas of the body are especially prone to hypertrophic scar and keloid formation, such as the chest, earlobes, and shoulders (Fig. 17-1). Black skin and children's skin also tend to scar more. Any patient at high risk for keloid formation should receive thorough preoperative counseling before proceeding with any skin surgery. These patients should be followed closely after surgery because early keloid development may be curtailed by the judicious use of steroid injections and silicone gel sheeting. As a general rule, the physician should avoid the temptation to excise keloids unless special attention is paid to preparation of the area before surgery using intralesional steroids, and the patient agrees contractually to long-term (1 to 2 years) surveillance and follow-up treatment if needed (see Chapter 38, Hypertrophic Scars and Keloids, for details). Conservative methods should generally be tried before reexcision, which potentially could just lead to more scars.

#### **EQUIPMENT**

Most skin excisions and closures can be performed with fairly simple equipment (as shown in the following list). Electrocautery and suction are not always necessary but are strongly recommended for meticulous control of bleeding. Adequate hemostasis is critical in preventing hematomas, wound dehiscence, and infection. Typical equipment should include the following:

- Topical antiseptic wash: povidone—iodine (Betadine) or chlorhexidine gluconate (Hibiclens)
- 5-mL syringe with needles (16 to 20 gauge to draw up anesthetic and 27 to 30 gauge for tissue injection)
- Injectable local anesthetic: 1% to 2% lidocaine with epinephrine for most areas; previously epinephrine has been avoided in fingers, toes, and genitals. However, newer findings would indicate that it is safe.

A 1:1 mixture of 1% lidocaine with 1% lidocaine with epinephrine works well in major revisions or flaps on the nose to minimize the excessive bleeding that often occurs without epinephrine. Epinephrine is not used, however, in an elderly woman with Raynaud's disease or poor nasal/facial circulation. It is always helpful to have the vasoconstrictive effect of epinephrine, but if flap viability is going to be a concern, it is best to limit or eliminate its use.

- Sterile drape
- Sterile gloves
- Sterile gauze pads
- Telfa pad and Tegaderm for wound dressing
- Skin-marking pen (Fine-tipped pens are available and suggested when more cosmetic repairs are important.)
- Nylon suture (4-0, 5-0, or 6-0, depending on location)

Figure 17-1 Keloid.

- 4-0, 5-0, or 6-0 absorbable suture such as Vicryl or Dexon if deep sutures are indicated
- Adson forceps
- Needle holder (smooth)
- No. 15 scalpel
- Suture scissors
- Two skin hooks
- Scissors, Metzenbaum, curved, 5 to 5½ inches
- Hemostats, curved, mosquito, 2 inches
- Hemostats, straight, small, 2 inches
- Good lighting

#### **Strongly Recommended Equipment**

- Electrocautery unit
- Suction device
- Crash cart including defibrillator, oxygen, and intubation equipment on site for emergencies (see Chapter 220, Anaphylaxis)

#### PREPROCEDURE PATIENT PREPARATION

#### **History and Physical**

During the preoperative history, topics of discussion should include the following:

- Medications, including herbal supplements, that the patient has taken in the past 6 weeks
- Allergies or adverse reactions to medications including iodine and local anesthetics, suture material, bandages, and latex
- Past surgical history and any history of keloid formation, hypertrophic scars, or poor wound healing
- Past medical history, including cardiac disease, diabetes, human immunodeficiency virus infection, hepatitis, bleeding disorders, immunosuppression
- Whether the patient has a pacemaker or other implanted electronic device that may preclude the use of electrocautery
- Whether the patient has a history of valvular disease, rheumatic fever, joint replacement, or other indication for antibiotic prophylaxis
- The status of any anticoagulants and when the last dose was taken
- Pregnancy (in reproductive-age women)

#### **Informed Consent**

Before the procedure, the patient must give informed consent to undergo surgery. This includes a full description of the risks, benefits, and alternatives to the procedure. The patient must have the opportunity to ask questions regarding the procedure and have the answers provided to his or her satisfaction to constitute informed consent.

Informed consent to photography is also recommended to allow a pictorial history. Either still or movie photography can be used.

#### Risks

The risks of the procedure to be discussed with the patient include, but are not limited to, the following:

- Suboptimal result, including the possibility of a worse scar after wound healing
- Infection
- Wound dehiscence
- Hypertrophic scar, keloid formation, or other poor scar result
- Swelling or bruising of the tissue
- Bleeding
- Pain
- Damage to nerves
- An allergic reaction to sutures, dressing, anesthetic, or other medications
- Recurrence of lesion and possible need for further surgery

#### **Benefits**

Benefits of the procedure may include, but are not limited to, the following:

- Improved cosmetic result
- Improved wound healing
- Improved overall results compared with conventional side-to-side closure
- Removal of potentially dangerous lesion such as squamous cell carcinoma, basal cell carcinoma, or melanoma

#### **Alternatives**

Alternatives to the cosmetic surgical closures listed previously may include the following:

- Leaving the wound open to heal by secondary intention
- Side-to-side closure
- Performance of a skin graft
- Referral to a plastic surgeon

#### **ANTIBIOTIC PROPHYLAXIS**

See Chapter 222, Prevention and Treatment of Wound Infections. Surgical antibiotic prophylaxis should be used more liberally when flaps and plasties are performed because the blood supply is often compromised with these closures, increasing the risk of infection. Antibiotic prophylaxis should be strongly considered in the following cases:

- The surgical site involves an extremity or ear, and when it is difficult to keep the area clean such as the axilla, the perineum, genitalia, and other intertriginous areas (e.g., under the breasts)
- Diabetes or immunosuppression
- The wound is dirty, has been open more than 1 hour, or aseptic technique was not ideal
- Patient follow-up is difficult, or the patient is otherwise at increased risk of infection
- History of previously infected wounds for no apparent reason
- Male patients 6 to 16 years of age

### PREOPERATIVE MEDICATIONS AND ANESTHESIA

The decision on whether to use sedation should be based on personal philosophy, patient desire, and the availability of proper monitoring. When performed correctly, most minor surgical procedures can be completed with minimal discomfort to the patient.

However, some sedation may be indicated in anxious patients when the procedure is extensive or if significant discomfort is anticipated (see Chapter 2, Procedural Sedation and Analgesia).

The use of local anesthetic warrants discussion. Lidocaine with epinephrine is preferable to lidocaine alone for nearly all cutaneous procedures. See the discussion regarding the use of epinephrine in the digits and end artery areas in Chapter 4, Local Anesthesia. In the doses administered in local anesthesia, epinephrine is generally safe and its vasoconstrictive properties are important in controlling bleeding and potentiating analgesia. Because epinephrine takes 7 to 10 minutes to achieve full effect, it is advisable to anesthetize the surgical site before preparing and draping the patient. The addition of 1 mL of sodium bicarbonate to every 9 mL of lidocaine with epinephrine helps neutralize the acidity of the solution and thus decreases the pain with injection. The addition of sodium bicarbonate to plain lidocaine does not benefit to the same extent because plain lidocaine is not as acidified. Bupivacaine (Marcaine) precipitates at a neutral pH and should never be used with sodium bicarbonate. When the longer-acting properties of bupivacaine are desired, it may be helpful to anesthetize the region using lidocaine with epinephrine (buffered with sodium bicarbonate) before injecting bupivacaine.

Additional techniques to minimize discomfort include the use of topical anesthetics, cryoanesthesia (e.g., topical ethyl chloride), slow injections, and initiation of the anesthesia injection on the subdermal plane. It is advisable to draw up all injectable medications in advance and to keep scalpels, needles, and syringes out of the patient's view, particularly when working with pediatric patients.

#### PREPARATION OF SKIN AND HAIR

Hair removal at the surgical site may be accomplished by shaving or by cutting the hair with scissors (to minimize microabrasions that may increase the risk of infection). On the scalp, ointment can be used to spread the hair away from the operative site and to minimize the need to cut the hair. The skin is prepared with a povidone—iodine (Betadine) or chlorhexidine (Hibiclens) solution with gentle scrubbing. Note that Betadine must be allowed to dry before it is considered effective, and Hibiclens should be avoided on the face because it is extremely toxic to the eye. Skin markings may be made before or after preparing the patient. An overzealous scrub or an alcohol wipe, however, may remove preoperative markings, and a pen used before the skin preparation is no longer sterile.

#### **DRAPES**

Sterile drapes should be used with any skin procedures that require suturing to protect the suture material from becoming contaminated and introducing bacteria into the tissue. Fenestrated drapes that have adhesive around the opening to affix the hole securely over the surgical site are especially helpful. However, you may need to extend the aperture or design your own by cutting a hole in a sterile surgical drape. Sterile technique is particularly important with flaps and plasties because blood supply may be compromised, predisposing the wound to infection.

#### **TECHNIQUE**

Also see Chapters 22 through 25, which cover various types of laceration and incision repair.

Tissue excision should be completed before committing to any particular flap or closure method. It is best to cut the shape of the defect, as well as the flap design, on a cotton towel before cutting the skin. This helps to prevent the common pitfall of creating flaps that are too short. The practitioner need not be limited to the following techniques. Some wounds may even heal best through secondary intention.

It is often preferable to convert a nonelliptical defect, such as a large punch biopsy site, to an ellipse along skin tension lines before

closure. On occasion, a nonelliptical defect such as a triangle or rectangle may lend itself to a flap closure by advancement or rotation. Regardless of the shape of the defect, the base must be on an even plane in the subcutaneous tissue to allow for a good result.

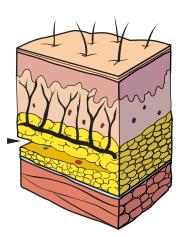

The key to good wound closure is to provide optimal alignment of the skin edges under minimal tension. High-quality wound closures are best accomplished by adequate undermining of tissue, the use of Burow's triangles, the appropriate use of corner sutures, and selection of the proper plastic closure for the defect or lesion to be removed. The desired effect is to produce an excellent skin closure with little or no tension. By performing a layered closure, tension forces that tend to pull the skin apart can be diverted to the deep structures, limiting scarring on the visible surface area. All buried sutures, if necessary, should have the knot inverted (placed away from the skin side). Most skin sutures should be removed within 7 days to prevent the formation of "railroad track" scars. Exceptions are back and anterior tibial areas, which may require removal of sutures at 14 to 19 days because of the slow healing of those areas.

Flaps are composed of skin and subcutaneous tissue cut from the donor site and moved a small distance to a recipient site without removing it from its vascular supply. Local skin flaps consist of rotation flaps that pivot into place and advancement flaps that move laterally. Rotation flaps maintain a base of intact skin, whereas some advancement flaps are completely incised, with blood being supplied only from the subcutaneous tissues. Because flaps carry their own blood supply, it is important to avoid damaging the subdermal vascular plexus or cutting potential nutrient vessels. Flaps created with parallel incisions are at increased risk for necrosis because of limited blood supply, but they are sometimes unavoidable. Figure 17-2 illustrates the proper level for undermining the flap tissue.

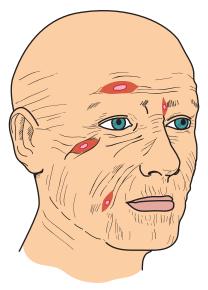

Tissue handling techniques are important for flap success. It is crucial to handle skin gently with minimal trauma. Lifting the skin with skin hooks is preferable to manipulation with forceps or pickups. Use skin forceps primarily for avascular structures and grasping needles, not for grasping the skin. Skin forceps are capable of exerting forces of greater than 400 pounds per square inch, which will bruise the repaired area and increase the likelihood of skin infection with a poor healing response. If grasping the skin is absolutely necessary, grasp the deep dermis only and avoid the fragile epidermis. Skin forceps without teeth are preferable.

#### **Elliptical Excisions**

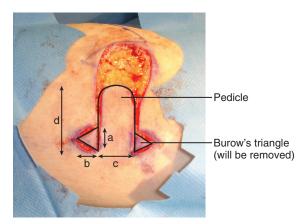

The elliptical excision technique is appropriate for the vast majority of lesions requiring tissue removal, and it generally facilitates wound closure. Length and width ratios should be greater than 3:1, and

**Figure 17-2** Skin flap (*arrowhead*), with proper level of undermining in subcutaneous adipose layer. This can be performed with a blade or sharp tissue scissors. It is important to maintain integrity of vessels and not create a flap that is too thin.

**Figure 17-3** It is essential to place elliptical excisions in relaxed skin tension lines.

**Figure 17-4** Burow's triangle: a, base of Burow's triangle; b, height of triangle; c, base of pedicle; d, length of pedicle. In planning Burow's triangle, the height (b) should equal half the base of its pedicle (c). The base of the triangle (a) should be one-third the length of the pedicle (d).

the terminal angles should be less than 30 degrees to avoid dog-ears. The long axis of the ellipse should run along wrinkle lines or, in younger patients, relaxed skin tension lines (Fig. 17-3; see Chapter 21, Incisions: Planning the Direction of the Incision).

If the closure is tight, gentle undermining may create more laxity. With flaps and plasties, some undermining will almost always be necessary. *Undermining* should be performed subdermally (between the skin and subcutaneous adipose tissue) to avoid injury to the vascular plexus (see Fig. 17-2 and Chapter 22, Laceration and Incision Repair). It is critical that the surgeon understands and uses undermining.

#### Description of Burow's Triangle

When side-to-side closure is difficult owing to skin tension, a variety of flaps can be used to close the defect, depending on skin availability and anatomic location. Simple elliptical closures usually have their best results in removal of small defects. Larger defects are almost always closed with a better result and a much lower likelihood of dehiscence with advanced closures and flaps.

In addition to undermining, another concept that must be mastered is the *Burow's triangle*. Corner sutures (three-point or half-buried mattress sutures) should be used in closing the Burow's triangles and in attaching the free end of the pedicle to the defect site. The Burow's triangles' height should be approximately half the width of the pedicle, and their base should be approximately one-third the length of the pedicle (Fig. 17-4).

#### Single Advancement Flap

This flap is a viable consideration for defect closures on the trunk and thighs (Fig. 17-5). Advancement flaps are conceptually simple but have limited application because of the parallel incisions required, as well as the increased skin tension created. The single-pedicle advancement flap, with or without Burow's triangles, may be useful in highly vascular, elastic areas. All advancement flaps are moved laterally without any rotation. In planning the flap, remember that the length of a simple advancement flap should be two to three times the length of the defect to be closed, depending on skin laxity. On the face, flaps should not exceed a 3:1 length/width ratio. As with the planning of all flaps, it may be helpful to cut the defect as well as the planned flap design on a surgical drape or other material before cutting skin.

1. Use a skin-marking pen to draw the desired flap on the patient's skin. In the case of a single advancement flap, it may be preferable cosmetically, although not necessarily, to round the advancing edge, creating a U-shaped closure, depending on the defect

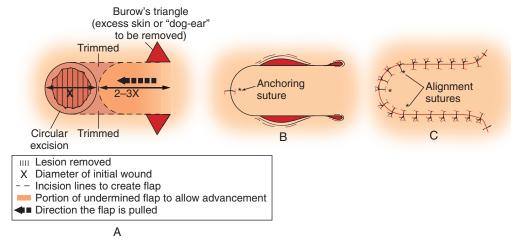

Figure 17-5 A-C, Single advancement flap. See text for details. \*, Anchoring suture.

- to be closed. At times, a rectangular end may be appropriate. Remember to make the base of the pedicle long and wide enough to avoid tension in the closure of the wound.
- 2. Undermine the intended flap at the level shown in Figure 17-2, and pull the flap into place.
- 3. Burow's triangles should be used to facilitate easy tissue movement and a closure with little or no tension. Burow's triangles should be placed at the pivot end of the pedicle on either side. This action greatly assists the operator in closing the wound.
- 4. Using the skin hook, advance the flap and place an anchoring suture. If the pedicle is rectangular rather than rounded, then corner sutures are critical to good position and healing (see Fig. 17-5B).
- 5. Place the next sutures as shown in Figure 17-5C to ensure proper alignment of the flap, then complete the closure.

#### **Double Advancement Flap**

Consider using double advancement flaps where *large defects are encountered on the trunk and the thighs*. If a double advancement flap is to be used (advancing a flap from two sides), the length of each flap should generally be one to two times the length of the defect.

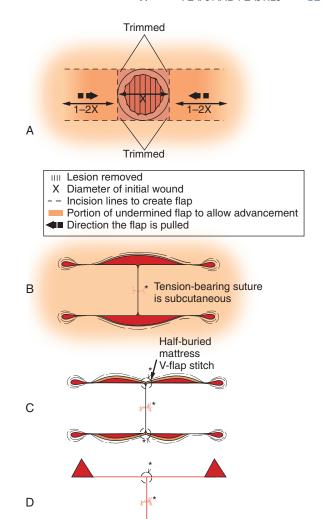

- 1. Excise lesions with appropriate margins.
- 2. Draw out the anticipated repair with the skin-marking pen and create the incisions as shown. Trim the excess tissue to create a square defect (Fig. 17-6A).
- 3. Undermine areas to be advanced.
- 4. Place a Burow's triangle on both sides on both pedicles, similar to the single advancement flap. These Burow's triangles should be the following dimensions: the base should be one-third the length of the pedicles, and the height should be one-half the width of the pedicles.
- 5. Advance the opposing flaps toward each other and place the anchoring (tension-bearing) suture subcutaneously (Fig. 17-6B).
- 6. Use double corner sutures (three-point/half-buried mattress) at sites where the flaps meet each other and adjacent to normal skin (Fig. 17-6C).
- 7. Place corner sutures where the Burow's triangles were removed (Fig 17-6D).
- 8. Close the remainder of the wound site with simple interrupted sutures (Fig. 17-6E).

#### V-Y Plasty or Island Advancement Flap

These closures are satisfactory for areas with excellent subcutaneous blood supply. The V-Y plasty or flap is an advancement flap that may be used in closing a circular defect. The technique should be limited to skin that is highly mobile. The technique may be useful when a vital structure prevents the standard elliptical excision or when an elliptical excision is too large to be closed without excessive tension (Figs. 17-7 and 17-8). There is a reasonable likelihood of loss of part of these flaps if the procedure is not done in a meticulous fashion. For larger lesions, the V-Y flap may be advanced from both sides as a double V-Y advancement flap. The disadvantage of the V-Y flap is that the entire perimeter of the triangle is incised, which severely reduces the blood supply to only the vessels coming up from beneath the flap and thus limits the distance the flap can travel.

Use of the V-Y flap to close a circular defect is demonstrated as follows (see Fig. 17-7):

- 1. Excise the defect (Fig. 17-7A and B).
- 2. Plan a triangle with a base approximately the diameter of the circular defect and an apical angle of 30 to 45 degrees (Fig. 17-7C).
- 3. Incise the triangle and undermine laterally to allow eventual closure of the sides. *Do not* undermine under the flap itself

**Figure 17-6 A–E,** Double advancement flap. See text for details. \*, Anchoring sutures. For further information, see Chapter 22, Laceration and Incision Repair.

Ε

because the blood supply to the "island" is provided by the subcutaneous vessels (Fig. 17-7D).

- 4. Trim the angles at the base of the triangle to fill the defect (Fig. 17-7F).
- 5. Using skin hooks, advance the flap into the defect and suture the top together (Fig. 17-7F).
- 6. Close the remainder of the incisions with simple interrupted sutures to create a Y-shaped scar (Fig. 17-7G).

Another method of creating a V-Y repair to close a wound under tension is as follows:

- Create an elliptical excision large enough to remove the lesion (Fig. 17-7H).
- 2. A V-shaped incision is made, then undermined to reduce skin tension (Fig. 17-7I).

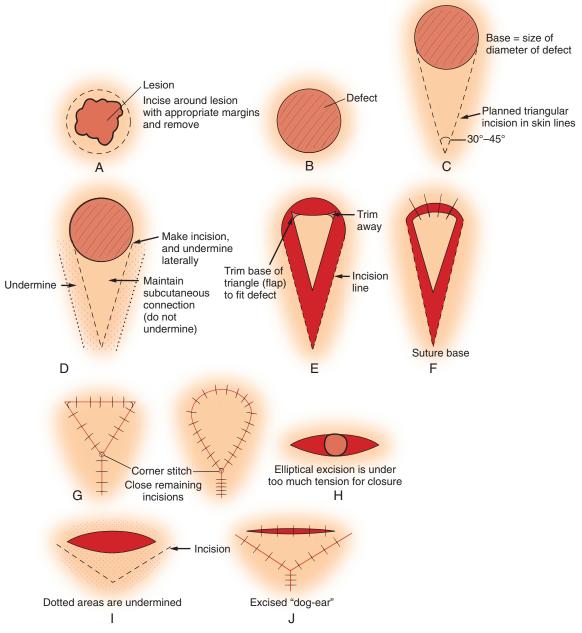

Figure 17-7 A-J, V-Y flap. See text for details.

3. Close the ellipse first. When the V is closed, there will be a dog-ear that will need to be excised. Closing this area will form the vertical portion of the Y (Fig. 17-7J).

The *double V-Y advancement flap* is performed in the same manner but with mirror-image triangular flaps that are advanced toward each other. This technique may be helpful for larger lesions.

- Mark an elliptical area around the lesion. Excise only the abnormality in a circular fashion (Fig. 17-9A).
- 2. *Incise* the triangular flaps that were marked out previously. *Undermine laterally only*, not under the "triangles." Using skin hooks, gently advance the two flaps toward each other and place the anchoring suture (Fig. 17-9B).
- 3. Place the next sutures as shown to provide good alignment, followed by corner sutures. The closure may then be completed with subcutaneous or simple interrupted sutures (Fig. 17-9C).

#### **Rotation Advancement Flap**

The design of a rotation flap should be planned only after the original tissue has been excised completely. The flap length should be generous (usually an arc length of four to five times the base of the defect to be closed) to allow adequate tissue movement. The advantages of a rotation flap include the provision of good blood supply by avoiding parallel incisions, the ability to undermine the mobilized tissue if needed, and the ability to create a contralateral flap if more tissue is needed. The major disadvantage is that the final result may not blend into natural skin lines. This closure allows the coverage of large defects if used correctly. Some tissues like the face rotate easily. The scalp also closes satisfactorily with this approach. This is an effective closure in the neck region and most other areas where loose skin can be moved to an adjacent area requiring a defect to be closed.

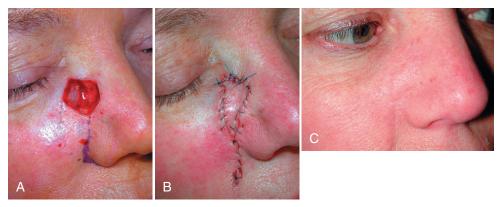

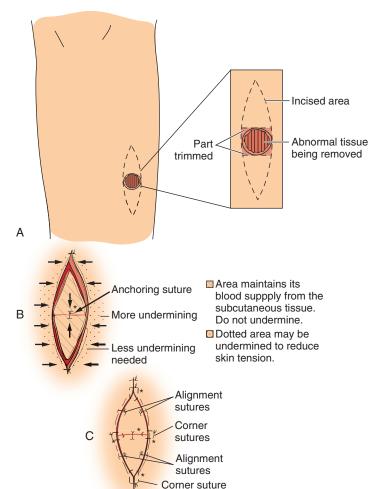

Figure 17-8 Island pedicle flap technique. **A,** Island pedicle repair of perinasal cheek defect. The flap can be advanced a great distance on a nasalis muscular swinging pedicle, which provides reliable blood supply. **B,** Note that although the flap was undersized, the surrounding tissues were undermined, and the flap was inset at the time of repair. **C,** There is slight flap elevation, a trapdoor deformity, at 6 months. (From Robinson JK, Hanke CW, Siegel DM, Sengelmann RD [eds]: Surgery of the Skin: Procedural Dermatology. Philadelphia, Mosby, 2005.)

- 1. The illustrated lesion lends itself to an excision that may be trimmed to create a triangular defect (Fig. 17-10A).
- 2. Draw the desired arc down to the "pivot point," according to the aforementioned guidelines (i.e., flap edge four to five times the length of the base of the triangular defect). Be sure to allow recruitment of sufficient tissue. Again, it may be helpful to cut the defect in a surgical drape, along with the proposed repair flap design, before incising the skin and committing to a particular repair (Fig. 17-10B). It is always helpful to first carefully draw the
- arc, lesion defect expected, and the Burow's triangle before any incisions are made. Excise the tissue to be removed.
- 3. Undermine the flap and surrounding tissue with curved Metzenbaum scissors or a blade (Fig. 17-10C). Make the Burow's triangle on the opposite side of the arc and at the other end of the arc. The Burow's triangle allows you to easily move the tissue of the flap into place (Fig. 17-10D).
- 4. Rotate the flap into place to fill the defect. The first suture is a corner suture reapproximating the skin at the corner of the Burow's

(half-buried mattress)

**Figure 17-9 A–C,** Double V-Y advancement flap.  $\ast$ , Anchoring sutures. See text for details.

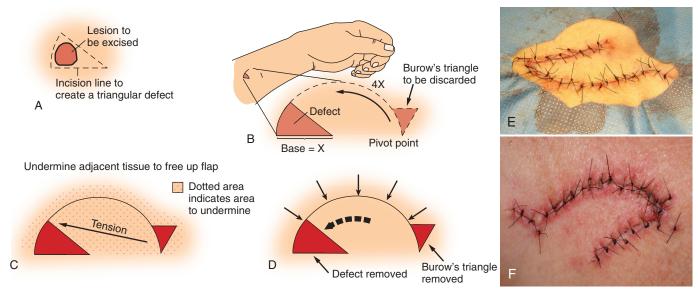

Figure 17-10 A-F, Rotation flap. See text for details.

triangle, and the second suture is the corner suture to connect the mobile end of the rotation flap to the other corner (Fig. 17-10E).

5. Suture the rest of the skin edges into place with simple interrupted sutures (Fig. 17-10F).

#### **Z-Plasty**

The best sites in which to use this closure are over flexor and extensor joints of the hand and the sacral area, where pilonidal cysts occur. The Z-plasty is a particularly useful technique for scar revision to redirect

a scar into skin tension lines (making it less visible) or to release scar contractures. Scar contracture is apt to occur when a laceration is perpendicular to skin creases, as in the case of a vertical laceration on the finger (Fig. 17-11A). Healing often contracts the scar, pulling the finger into a flexed position. Redirection of the scar can release skin tension. The major drawback to the technique is that the length of the scar is increased.

1. Excise the linear scar or lesion in a narrow ellipse along its axis (Fig. 17-11B).

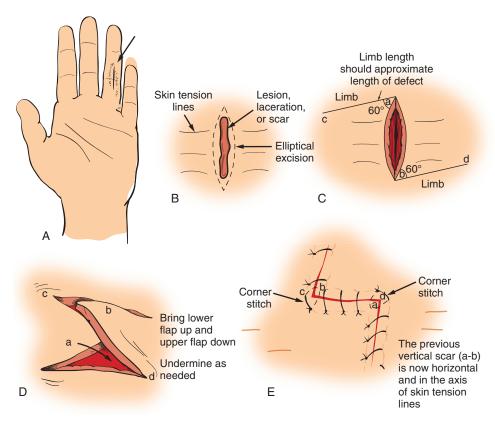

Figure 17-11 A-E, Z-plasty. See text for details.

- 2. Create the limbs of the "Z" at 60-degree angles from this axis. The length of each limb should equal the length of the defect (Fig. 17-11C).
- 3. Using skin hooks, advance the two triangles as shown, by crossing them over one another (Fig. 17-11D). Undermine the flaps as needed.
- 4. Place a "corner stitch" (half-buried mattress) at each of the flap tips, as shown in Figure 17-11E. Then complete the wound closure with simple interrupted sutures. The new scar will now lie within the axis of the skin tension lines.

#### **M-Plasty**

This is an excellent closure when there is a paucity of skin for rotation or advancement flaps and can be used on the face, scalp, neck, trunk, and extremities. It is truly a closure suitable for all areas and produces excellent results when the rules are followed. The design of this repair should be based on Langerhans' tension lines so the final closure is parallel with Langerhans' lines. The blood supply is excellent, and it is rare to lose any portion of the flap because of inadequate blood supply. The repair usually blends into the skin lines very well with time.

- 1. The lesion should lend itself to a linear-type closure. The outline of the lesion to be removed should fit into the center of the M-plasty drawing (Fig. 17-12A and B). The length/width ratio should be at least 3:1, with the length measured at the internal points of the Burow's triangles and the width being the total width of the excision (lesion plus margins). This is an extremely important measurement.
- 2. The base of each Burow's triangle should be approximately the same as the depth (height) to allow ideal closure. There certainly

- is room for variance and still get a good closure, but these guidelines are the best.
- After the M-plasty is drawn on the skin, allowing adequate margins, the entire lesion and excess skin are removed (Fig. 17-12C).
- 4. The next step is to carefully undermine the surrounding tissue at the same depth as the lesion removed. The area to be undermined is usually about 10 mms, but it needs to be approximately equal to half of the width of the skin excised, with the undermining to be extended around the entire perimeter, including beneath the Burow's triangles at each end of the M-plasty.
- 5. The first suture placed is an anchor suture in the middle of the repair to bring the edges together (Fig. 17-12D). If the wound does not come together easily, then the undermining was inadequate or the 3:1 ratio was not upheld.
- 6. The second and third sutures to be placed are placed midway between the anchor (middle) suture and either end of the wound to be closed (Fig. 17-12E).
- 7. The fourth and fifth sutures to be placed are modified corner/subcuticular sutures placed near the end of the wound from each side into the subcuticular portion of the skin, then connecting the tip of each Burow's triangle (through the subcuticular tissue), then out through the subcuticular tissue on the other side and out the skin opposite the entry point on the opposite side of the wound. The suture through the skin should be placed about 2 to 3 mm central to the point of the Burow's triangle to allow a gentle pull of the triangle toward the center of the wound (Fig. 17-12F).
- 8. The other sutures needed are simply interrupted sutures to produce the appropriate closure.
- When the sutures are removed, it is best to leave the anchor suture as the last one to be removed if the sutures are removed sequentially (not at the same time).

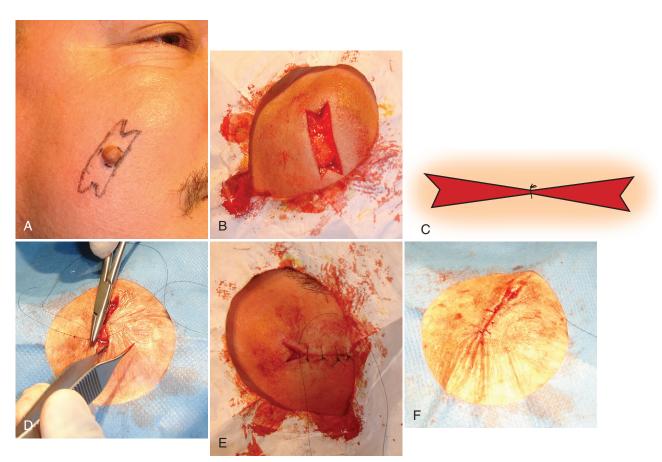

Figure 17-12 A-F, M-Plasty. See text for details.

#### **Dog-Ears**

Dog-ears are caused by excess skin left at the end of the suture line. They commonly occur when skin edges are rotated or pulled, when interrupted sutures are not placed evenly, or when one side of a wound is longer than the other. Dog-ears can be avoided by (1) closing the ends of an elliptical defect first and distributing the "extra skin" throughout the wound, (2) keeping ellipse incision angles 30 degrees or less, and (3) maintaining 3:1 length/width ratios or using advanced closures. The best technique for repair is demonstrated in Figure 17-13. In this repair, the wound will be lengthened and excess tissue must be removed.

It is easy with this technique to judge the amount of tissue that must be removed.

- 1. Excess tissue on one side of the wound closure creates a dog-ear (Fig. 17-13A).
- 2. At the apex of the wound, incise the tissue at a 150-degree angle to the wound. The length depends on the amount of excess tissue (Fig. 17-13B). Make the cut on the side of the wound where the excess tissue exists, making sure that you gently pull the excess tissue toward the wound along the long axis of the wound.
- 3. Using the skin hook, pull the apex of the dog-ear over the extended incision line and excise the excess tissue with a blade or tissue scissors (Fig. 17-13C). This action makes the repair close nicely using the Burow's triangle approach.
- Close as shown using a corner suture and then interrupted sutures (Fig. 17-13D).

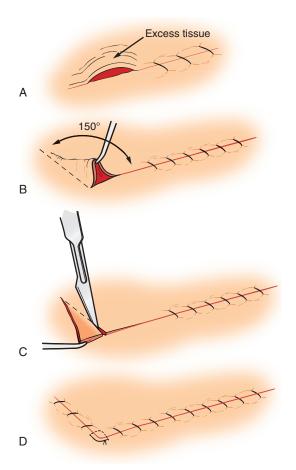

Figure 17-13 A-D, Dog-ear repair. See text for details.

### POTENTIAL COMPLICATIONS OF ADVANCED CLOSURES AND FLAPS

#### Acute (within 2 Weeks)

- Bleeding
- Bruising
- Swelling
- Hematoma
- Pain
- Infection
- Wound dehiscence

#### Chronic or Permanent

- Scarring/contractures
- "Railroad tracks" from delayed suture removal
- Hypertrophic scars
- Keloid
- Hyperpigmentation
- Hypopigmentation
- Nerve damage
- Ectropion and entropion of eyelid
- Disruption of vermilion border of upper lip
- Skin atrophy
- Hair loss
- Recurrence of excised lesion

#### **Additional Considerations**

In the excision of potentially malignant lesions, tumor-free margins must always be obtained before committing to any flap closure. If a later pathology report indicates incomplete excision of a malignant lesion, the appropriate area around the previous closure area will need to be resected. If this involves a flap technique, there may already be significant skin tension or little skin may be available for further repairs. The patient requiring more extensive repairs or grafting may be left with a large defect. But usually, with a correct surgical approach, reexcision to accomplish a cure based on pathology should be possible.

#### POSTPROCEDURE PATIENT EDUCATION

Proper postoperative care is more critical with skin flaps and plasties than with simple closures. For the first 24 hours after surgery, the patient must rest and avoid exertion. Instruct the patient to refrain from bending, heavy lifting, and exercising until the sutures are removed. The wound should be kept clean and covered with a thin coat of antibiotic ointment particularly for first 24 hours. The patient should refrain from alcohol and aspirin-containing medicines for at least the first 24 hours after surgery. The wound should be dressed with a small piece of Telfa covered by Tegaderm or roll dressing, depending on the site, so a good seal develops over the wound. If subcuticular sutures are used, Steri-Strips are placed, followed by the Telfa and Tegaderm dressing. A thick outer dressing of  $4 \times 4$  gauze or other bandage is then placed to provide a pressure dressing that limits bleeding and swelling. Ice on the area for 2 to 4 hours helps relieve pain, swelling, and bleeding.

After 24 hours the thick outer bandage may be removed. Most wounds heal faster and are less likely to develop secondary infection if left open. Each day the wound should be carefully checked to make sure there is no crust or blood accumulation. If there is blood or crust accumulation, this should be removed with gentle washing using soap and water. The wound should have a very thin layer of antibiotic ointment applied before bedtime. The exceptions to these guidelines are hand and foot wounds in boys or men who will continue to work and play. These selected patients should continue to have a wound covering at least during the daytime after the first 24

hours to keep the wound from getting wet or contaminated. If the wound dressing gets wet or contaminated, it should be replaced with a new dressing of antibiotic and Tegaderm or roll dressing. After 24 hours it is acceptable to shower and wash the wound. The area should not be scrubbed. If the wound bleeds at any time, the patient should apply firm pressure for 15 minutes and a new dressing should be placed over the wound. Instruct the patient to call the office or go to the emergency department if the wound bleeds significantly despite 15 minutes of firm pressure, if any signs of infection (e.g., purulence, redness, increased pain, swelling, or fever) are noted, or if there is any breakdown in wound or suture integrity.

In the case of surgery on the face, instruct the patient to sleep with his or her head slightly elevated for the first two nights after the procedure and to avoid sleeping on the same side as the wound. The patient should also avoid bending down (head below the heart) for the first 48 hours after the surgery. Arrange for office follow-up based on personal discretion, depending on the complexity of the procedure, the cleanliness of the wound, and patient factors. Sutures on the face are usually taken out within 4 to 7 days, depending on the size, position, and tension of the closure. If deep, buried sutures are used, skin sutures may be removed sooner than if no buried sutures are used. Sutures on the neck are generally left in place for 6 to 8 days depending on the size and tension of the closure. On the trunk, groin, and extremities, sutures are left in longer, usually 10 to 21 days, depending on the speed of healing. Usually the slowest areas to heal are the anterior tibial areas and the posterior trunk. Sutures on the scalp are usually removed in 7 to 10 days.

#### **CONCLUSION**

Achievement of a durable repair with a good cosmetic result after skin surgery is important. To obtain predictable, good-quality outcomes, focus on simplicity. An ellipse excision with primary closure is best used for small lesions. Other, larger defects, skin cancers that require wider excision, and any area that is likely to dehisce is usually much better served with a plastic/flap repair if done correctly. When wounds are difficult to close, flaps, skin grafts, and healing by secondary intention are always options, and usually better options for optimal long-term results.

It is prudent to remember the keys to excellent repairs in plastic closures: (1) proper width-to-length ratio of excision, (2) corner sutures placed appropriately, (3) undermining done carefully with Metzenbaum scissors, and (4) use of Burow's triangles to extend and move tissue. Observance of these four parameters will provide optimal outcomes.

#### **PATIENT EDUCATION GUIDES**

See the patient education and consent forms available online at www.expertconsult.com.

#### **CPT/BILLING CODES**

Excision or repair by adjacent tissue transfer or rearrangement, including Z-plasty, V-Y plasty, rotation flap, and advancement flaps:

14000 Trunk <10 sq cm

14001 Trunk 10-30 sq cm

14020 Scalp, arms, legs <10 sq cm

14021 Scalp, arms, legs 10–30 sq cm

14040 Forehead, chin, cheek, mouth, neck, axilla, genitalia, hands, feet <10 sq cm

14041 Forehead, chin, cheek, mouth, neck, axilla, genitalia, hands, feet 10–30 sq cm

14060 Eyelids, nose, ears, lips <10 sq cm

14061 Eyelids, nose, ears, lips 10–30 sq cm

14300 Any area, unusual, or complicated repair, more than 30 sq cm

14350 Filleted finger or toe flap, including preparation of recipient

**NOTE:** These codes generally apply to full-thickness excision and repair by adjacent tissue mobilization. For reporting laceration repairs, the procedure must be created by the surgeon and not by the incidental shape of the laceration. Refer to the CPT book for further description.

#### **ICD-9-CM DIAGNOSTIC CODES**

See Appendix G, Neoplasm, Skin: ICD-9 Codes.

# FOREIGN BODY REMOVAL FROM SKIN AND SOFT TISSUE

Grant C. Fowler

Patients frequently seek care from a primary care clinician for a foreign body in the skin or soft tissue. In fact, foreign bodies are present in 3% of wounds. In certain situations, removal may cause more trauma than leaving the object in place; hence, the patient may require only information or reassurance. However, the presence of a foreign body increases the risk of infection in most wounds, even if only slightly. A foreign body can also cause pain. Fortunately, removal is often accomplished with minimal trauma, usually resulting in considerable appreciation by the patient.

A foreign body should be suspected in all wounds caused by a high-velocity missile or a sharp, fragile object. Objects that splinter, shatter, or break in the process of causing a wound often leave remnants behind. For example, a piece of glass that caused a wound by breaking on impact with the skin is more likely to leave shards in the wound than a piece of glass that was previously broken.

All wounds should be probed manually for the presence of a foreign body. Up to 38% of embedded objects are missed on the initial assessment; consequently, the most common error in the management of soft tissue foreign bodies is the failure to detect their presence. Failure to diagnose soft tissue foreign bodies and manage them correctly is a common cause of malpractice litigation in both emergency and family medicine. With the techniques discussed in this chapter, attempts at removal may be simplified and the results optimized.

#### **INDICATIONS**

- Known foreign body in skin, subcutaneous, or soft tissue
- Pain or persistent inflammation from a foreign body
- Foreign body with toxic, infectious, or allergic potential
- Impairment of neurovascular or mechanical function due to a foreign body
- Foreign body near a fractured bone or open joint
- Foreign body causing a cosmetic deformity

NOTE: A general guideline is if one end of the foreign body can be palpated by hand or an instrument, it can be removed. Another is that removal may be more difficult than expected, even if the foreign body is large, palpable, and apparently superficial on radiographs; therefore adequate time should be set aside to evaluate, explore, plan, and pursue removal. However, some experts say spend no more than 15 to 20 minutes exploring; clinicians thereby avoid causing excessive damage by probing for too long "looking for a needle in a haystack." Yet another guideline is if a patient complains of a foreign body sensation, the clinician should assume that there is one, even if the radiographs are negative. One study found that a foreign body sensation in a patient was 43% sensitive and 83% specific for the presence of glass.

#### **CONTRAINDICATIONS**

- Lack of knowledge of anatomic structures surrounding the foreign body
- Proximity of foreign body to a vital structure such as a nerve or artery
- An uncooperative patient who cannot be sedated (see Chapter 7, Pediatric Sedation and Analgesia) or anesthetized (see Chapter 4, Local Anesthesia)

**NOTE:** Consider referral for a foreign body in the soft tissues of the face or the deep spaces of the hands or feet, or for broken glass if there are multiple shards. Also, deeply imbedded objects, those in joints, and those impairing neurovascular or mechanical function may best be removed by a surgeon while the patient is under general anesthesia.

#### **EQUIPMENT**

- Blunt-tipped, stiff (but bendable), sterile metal probe
- Small, sharp-tipped dissecting scissors
- Sterile tweezers (splinter forceps are very helpful)
- Adson pickup forceps with teeth (an Allis clamp may also be helpful)
- Two mosquito hemostats
- Bright light that can be directed or focused (use of a headlamp allows both hands to be free for the procedure)
- Clear plastic tape
- Skin-marking pen or pencil
- Paper clips, BBs, or 27-gauge needles used for local anesthetic can be used as markers
- Scalpel (no. 11 or 15)
- Suture, if necessary for closure
- Local or topical anesthetic materials (see Chapter 4, Local Anesthesia, and Chapter 10, Topical Anesthesia)
- Irrigant, such as saline
- Syringe for irrigation (5 mL for small wounds, 10 to 30 mL for larger wounds) with optional 18-gauge needle
- Magnifying glass or loupes
- Povidone-iodine solution (Betadine)
- Powerful magnet for ferromagnetic objects
- Sterile adhesive bandage
- Liquid soap
- Blood pressure cuff to use as tourniquet and elastic (Ace) bandage (optional)
- Hair removal (depilatory) wax (optional)
- Skin hook (optional)
- 3-mm skin punch for biopsy (optional)
- 1-0 or 2-0 nylon suture, without needle, to use as probe (optional)
- Hemoclips, hemoclip applicator, and silk sutures (optional)

#### PREPROCEDURE PATIENT PREPARATION

Patients should be aware that in some situations removal may be too complicated, unsuccessful, or impossible. The clinician should also explain that it is safe for certain objects to be left in the skin permanently. For example, wounds containing a small metal fleck in a nonvital area will often heal with no problems. Even lead and other metal objects are sometimes safe to let "rest" in the skin indefinitely. Their removal, especially if deeply embedded, may cause more trauma than leaving the object in place, especially if the patient is not experiencing symptoms and has no signs of infection. The body tends to wall off nonporous materials and smooth objects such as bullets, glass, metal, and even shrapnel; therefore, if deeply embedded they are often better left alone. However, heavily contaminated foreign bodies should be removed as soon as possible. Hair or marine foreign bodies, such as sea urchin spines, may cause granuloma formation, so they should usually be removed. Similarly, objects made of wood, vegetable fiber, or other organic materials, which are likely to cause an inflammatory reaction or infection, usually have to be removed. The same is true for any object with toxic or allergic

Patients should also be aware that it may be necessary to leave the object in the tissue until it forms a cyst or localizes (i.e., edema subsides). Although it may take days, weeks, or even decades, certain objects will eventually work their way to the surface and can then be removed. If an infection develops, it will be treated with an antibiotic. If a small pocket of fluid develops, it may help with later removal. Inform the patient that if removal is attempted, certain techniques may be used to locate and remove the foreign body, including taking radiographs.

If removal is attempted, the patient should be informed that there is a chance that the object will not be able to be removed or may be only partially removed. Even with what appears to be a simple extraction (e.g., splinter), the clinician may want to be cautious about telling the patient that it was removed entirely; perhaps a better explanation is that all of the visible object was removed but that there is always the chance that small fragments may still be present that are currently undetectable. With removal, there will be minor trauma and possibly scarring (from the original wound, an incision, or from sutures), and there is a possibility of damage to vital structures surrounding the object such as a nerve, artery, vein, or tendon. Such trauma may be associated with discomfort during the procedure or some bleeding during or after the procedure. There is also risk of infection after the procedure. In certain situations, minimal or no anesthesia will be used at first in order to localize or grasp the object. A patient's intact sensation is usually much more accurate than probing blindly under anesthetized skin when attempting to locate an object, especially if the skin were to be distorted from an injection of the local anesthetic. For small or difficult-tolocate objects, the patient's intact sensation may be the only way to find the object. As soon as the object is grasped, stabilized, or removed, the discomfort is usually decreased or eliminated. After the object is grasped, local anesthetic may then be used to minimize any discomfort.

The patient should be aware that glass objects, especially small ones, may be difficult to visualize on radiographs and that there may be multiple shards. For various reasons, glass is probably the most difficult object to remove. If the clinician is not certain that all of the foreign object(s) has been removed, referral may be required.

If the decision is made to attempt to remove the object(s), the patient should be aware that the procedure may be time consuming, although usually not more than 15 to 20 minutes will be spent exploring to keep tissue damage to a minimum. He or she should be in a comfortable position that can be maintained for this amount of time. The patient should also be aware of the importance of remaining immobile during the procedure.

#### **TECHNIQUE**

- Before removal, obtain as much history as possible regarding the foreign body. Knowledge of the material and method of injury may help determine which technique to use and whether a diagnostic study such as a radiograph would be helpful. Knowledge of the angle of entry (e.g., whether tangential or perpendicular to the skin surface) may be helpful for localization. Information regarding the speed and force of entry may also be helpful.
- 2. Most superficially embedded, visible objects can be magnified and removed from soft tissue with a sterile needle and tweezers. For very fine splinters in the skin surface (e.g., cactus spurs, glass slivers), spreading liquid soap lightly over the skin will often enhance visualization. Alternatively, they can be removed by applying clear plastic tape or hair removal wax to the skin and then peeling it off.
- 3. Good judgment should be used when removing foreign objects in cosmetically sensitive areas. For example, the risk of tattooing from an object left in place (e.g., graphite from pencil or asphalt, tar, or gravel from road) must be weighed against the risk of a scar from removal.
- 4. Toothpicks and splinters usually enter tangentially, and their tract can usually be envisioned based on the history. Occasionally, instead of using forceps or making an incision, a hypodermic needle can be inserted perpendicular to the splinter to "spear" the splinter. The hypodermic is then used as a lever to ease the splinter out through the entry wound. Because wood splinters must be removed entirely to avoid local inflammation, instead of merely pulling the splinter out, many experts incise the entire tract of the splinter to remove it. They then irrigate the wound to ensure removal of any and all fragments. Although this may seem excessive, and creates a laceration where only a puncture wound existed, small pieces of the splinter may otherwise remain in the skin. This is especially important for splinters derived from cedar or California redwood because of the pliable and reactive nature of the wood.
- If the object is not visible because it is below the skin, consider the use of radiographs or other imaging techniques for localization and documentation.
  - Radiographs are 98% sensitive for detecting radiopaque materials such as metal, gravel, pencil graphite, or teeth. Sand, mammalian bone, and certain fish bones (e.g., haddock, cod, grey mullet, sole, red snapper) are also usually radiopaque. Some plastics produce at least a slight shadow on x-ray films. Painted wood can also sometimes be seen on x-ray films. Although leaded glass is radiopaque, which improves its visibility on radiographs, the majority of glass is nonleaded. However, in one cadaver study, radiographs were 90% sensitive for detecting nonleaded glass, with a false-positive rate of only 10%. (It should be noted that a diameter of less than 1.5 mm was associated with risk of failed detection.) Radiographs are also helpful if the glass shattered near the skin surface to make sure there are not multiple shards. Routine lateral and anteroposterior views may suffice. By ordering "soft tissue" x-rays, slightly underpenetrated films are provided, which enhances visibility and localization efforts. (With digitized images, the contrast and brightness can be adjusted to produce the same effect.) If the object is positioned parallel to the central ray of the x-ray beam, it increases the likelihood of detection. Oblique and tangential views may also be helpful if the object is obscured by underlying bone.
  - High-frequency ultrasonography is available in most emergency departments as an alternative for localizing nonradiopaque objects (see Chapter 185, Musculoskeletal Ultrasonography, and Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography]). Most

authors have reported a greater than 90% sensitivity for detection of objects larger than 4 to 5 mm. Although ultrasonography has the benefit of avoiding radiation, it has the limitation of being operator dependent. Small objects perpendicular to the skin surface may also be difficult to visualize. The 7.5- to 10-MHz probe is better for shallow depths (<5 mm), whereas the 5-MHz probe should be used for deeper searching.

- Xeroradiography (technology used in xeromammograms), although recommended in the past, has fallen out of favor because it has rarely been found to offer an advantage over plain radiographs. It also requires a much higher dose of radiation compared with plain radiographs and is not as readily available.
- Fluoroscopy has received more attention lately as a diagnostic and therapeutic tool in the emergency department. Compared with plain radiographs, bedside fluoroscopy usually requires less irradiation and is faster, more convenient, and less expensive. For objects that must be removed, needle localization under fluoroscopy may remain the final option.
- Computed tomography (CT) scanning is useful not only for further characterizing foreign objects seen on plain radiographs, but also for diagnosing possible complications such as an abscess. CT is often useful for visualizing nonradiopaque objects made of plastic or wood. Consequently, CT has evolved as the procedure of choice for excluding foreign objects if the plain radiograph is negative. With the development of spiral/helical CT scanning (i.e., real-time scanning), and its increased availability in emergency departments, the time required to visualize an image has been greatly reduced.
- Magnetic resonance imaging (MRI) in comparison studies is the most accurate method of detecting foreign bodies such as thorns or those made of wood or plastic. MRI is also useful

- for detecting complications due to a foreign body such as an abscess or bony involvement. However, MRI is limited when scanning gravel or ferrometallic foreign bodies because they produce streaking that usually obscures visualization. And because CT scanning can also usually detect foreign bodies made of wood or plastic, and abscesses, MRI is rarely used because of the additional time it takes to obtain the images as well as the additional expense incurred.
- 6. Attempt to localize the object before incising the skin. Although the object may not be visible, there may be a discoloration beneath the skin. Any externally visible entry wound should be measured and the exact size and location recorded. Examine the wound entrance to determine the angle of penetration and possibly the depth of penetration. Palpate the object, determine the exact orientation and approximate depth (Fig. 18-1A), and measure and record it. For larger metal objects, a powerful magnet may pull the object to the surface and tent the skin. If the skin tents, mark the outline of the object with the skinmarking pen. Glass is the most common foreign body, yet it is one of the more difficult substances to remove because it is transparent and slippery, and the size and outline of the pieces are unpredictable. If glass is suspected, to avoid cutting yourself do not probe with your finger. An unknown number of shards may be involved, and if there is uncertainty about whether all of the shards have been removed, referral should be considered.

**NOTE:** Probing a wound with a gloved finger is not recommended for *any* possibly sharp foreign object because it may result in a puncture wound to the clinician and spread of a body fluid— or blood-borne infection.

7. If the object is not visible at the entrance wound, after palpation for orientation and depth, prepare the skin with povidoneiodine and carefully use a sterile probe or mosquito hemostat to

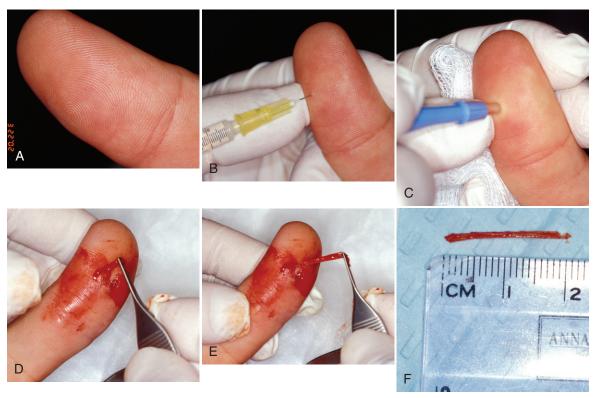

Figure 18-1 Patient reports sensation of sliver in palmar surface of distal phalanx. **A,** A fullness is palpable, but no real foreign body is detected. **B,** Lidocaine 2% 0.5 mL without epinephrine is injected. **C,** A 3-mm disposable skin punch is used. It is inserted until a gritty sensation is appreciated. **D,** Fine pickups without teeth are inserted and grasp the foreign body. **E,** A long wooden sliver is removed. **F,** The sliver.

enter the wound. Gently follow the apparent tract of the wound to locate the nearest edge. Use small, light, deliberate probing motions, gradually fanning in all directions, until contact is made with the object. This may be felt or heard as a clicking sound when the probe contacts the foreign body. (For metallic objects, a magnetic probe can be used in the same manner and the object will usually cause a click when it comes into contact with the magnet, and can then be pulled out of the wound.) Avoid excessive or unnecessary blind probing that may conceal the foreign body further with blood and edema, or push it deeper into the tissue. For small objects, before using local anesthetic, attempt to use the patient's sensation as a guide; it may be more accurate than using a probe. In this situation, avoidance of local anesthetic not only minimizes local skin distortion but limits the tissue destruction that may occur by cutting or exploring blindly under anesthesia. After the object is removed, if the patient has not been anesthetized and the symptoms have completely resolved, this is somewhat reassuring that everything was removed. If the patient continues to have a foreign body sensation, there may have been more than one foreign body and exploration may need to be continued.

- 8. If the object is not palpable, an attempt can be made to follow the tract of the wound with a probe. However, because of the nature of the tissue, following the tract may be more difficult in muscle or fat. That said, the clinician must avoid probing only superficially because the subcutaneous tissue can reapproximate and give the appearance of a superficial wound. If necessary, the wound edges should be extended with a scalpel for direct visualization if there is concern regarding a retained foreign body. If the bottom of the wound is less than 5 mm deep and visible, there is a 96% chance that a foreign body has been ruled out.
- 9. After the object is located, fixate the probe in the clinician's nondominant hand. Rest this hand on a firm surface. Administer or inject local anesthetic with the dominant hand (Fig. 18-1B). Occasionally, the injection of anesthetic beyond the foreign body or on each side of the entry wound will force the foreign body out. After excluding the presence of a neurovascular bundle, tendon, or other important structure, without moving the probe, cut down along the probe with a no. 11 or 15 scalpel blade until the foreign body is reached. Do not remove the probe. Reach into the incision and remove the foreign body with a pair of Adson forceps. Alternatively, if the entrance tract is fairly long, and if the foreign body is very superficial and easily palpable beneath the skin, it may be advantageous to simply cut down through the skin directly over the object to remove it without the use of a probe. The object should be stabilized between the fingers of the clinician's nondominant hand while the incision is being made.

NOTE: An inadequate incision is a common source of frustration when attempting to remove a foreign object, so the clinician should usually plan a slightly larger-than-necessary incision when making it. Bleeding into the field, which may obscure the entrance wound or the object, can be another source of frustration. If the object is in the soft tissue of an extremity and the arterial circulation is otherwise intact, it is safe to inflate a proximal blood pressure cuff to greater than systolic arterial pressure for up to 2 hours to minimize bleeding. (Although this may cause some mild patient discomfort, patients usually tolerate it well.) The extremity can be elevated for a minute or an elastic (Ace) bandage can be wrapped tightly around the extremity, from distal to proximal, before inflating the blood pressure cuff to minimize venous backflow into the field. The elastic bandage can be removed as soon as the blood pressure cuff is inflated.

 For a wound less than 48 hours old, one technique that has been found to have a 92% success rate uses nylon suture as a probe. The clinician grasps a 1-0 or 2-0 nylon suture (with no needle) between his or her thumb and index finger, then pushes it into the entrance wound while gently rotating it so that it follows the foreign body tract. Experienced clinicians report that the foreign body is easily felt when the suture contacts it. The suture is then left in the tract and the wound opened down to the foreign body by cutting alongside the suture with a scalpel.

11. If an edge of the object is somewhat superficial and easily located with a probe, and the entrance wound is large, simply enlarging the entrance wound slightly with mosquito forceps may provide the clinician enough room for a firm grasp on the object with the forceps. The object can then be removed. If the object has been in place for long enough to form a cyst, occasionally the cyst wall will need to be incised. This may be performed by the use of very small, deliberate strokes with the scalpel while the object is held by one set of mosquito forceps. The other set of mosquito forceps can then be used to bluntly dissect down to the object by spreading anything that was incised with the scalpel. If the object is visible after incision of the cyst wall, it should be grasped through the incision with the second set of forceps. The first set of forceps can then be relaxed and the object removed. If the object is not visible, which is often the case when a foreign body has been in place for a long time, constant traction on the object with the first set of forceps may cause one end of the cyst to tent. Incise through this tent with the scalpel until the object is freed.

**NOTE:** Do not blindly grab something in a wound with a hemostat. Blind grasping can cause damage to a vital anatomic structure.

- 12. Another option for the not vet visible but readily palpable object is to perform a punch biopsy (Fig. 18-1C through F; see Chapter 32, Skin Biopsy). As the punch biopsy is being performed, a hard "click" may reveal the position of the foreign body, thereby both localizing the foreign body and avoiding the need to make a larger incision. After the biopsy is performed, tease apart the core of tissue removed and identify the foreign body. If the foreign body cannot be found in the tissue, probe the wound to make sure the foreign body is not still beneath the biopsy site. If the punch biopsy missed the foreign body (because of an angled entry wound, it may be lateral to the biopsy site), undermine the subcutaneous fat all around the site using dissecting scissors. After undermining, if pressure is applied from various locations around the site toward the center of the biopsy site, it may force the foreign body into the biopsy site. Foreign bodies located in subcutaneous fat are highly mobile, so lateral pressure can move them a considerable distance. If the foreign body is beneath the biopsy site, the decision can be made whether to deepen the site with the punch or to cut down with a no. 11 scalpel. Neither procedure should be performed if the object is located close to an underlying vital structure (e.g., nerve, artery, significant vein).
- 13. If a skin punch is not available, a simple elliptical excision of a block of skin overlying the foreign body can be performed in the same manner. Limit the incision to just the skin, and while applying upward traction on the ellipse with forceps (or an Allis clamp) and with the subcutaneous fat still attached beneath, probe the subcutaneous fat lateral to and beneath the incision for the foreign object. If the object is not found with probing, use the dissecting scissors to undermine the subcutaneous fat in the same directions, attempting to come into contact with the object. If the object is not found with undermining, the probe can be used again under the ellipse or directed laterally. If the object is still not located, apply pressure to the skin lateral to the incision, attempting to force the object into view.
- 14. If the object is neither palpable through the skin nor able to be located by probing through the entry wound (yet is visible on

x-ray films), paper clips or BBs may be used for localization with a radiograph. Bend the paper clips into various shapes and tape them to the skin with clear plastic tape, or tape the BBs over the skin above and beside the approximate location of the object. With lateral and anteroposterior radiographs taken at precisely 90 degrees, the location of the foreign body can be predicted by measuring the distance from the paper clips or BBs on the film. Transfer this measurement to the skin with a marking pen. Next, remove the tape and clips, apply povidone-iodine and local anesthetic, incise the skin in the correct location to the depth measured on the x-ray film, and remove the object. A punch biopsy may also be used in this manner if the measurements from the x-ray film are very accurate; however, if there is any error in the measurement, an incision may need to be made to expand the search for the object.

**NOTE:** It is very important to have true lateral and anteroposterior views in order to use radiographic measurements for localization before incision; otherwise any variance in the angle of the x-ray beam to the film will cause significant distortion of the apparent location of the foreign body. This is especially true for small metal flakes.

- 15. For deeply embedded objects, after injecting local anesthetic, two 27-gauge needles can be inserted at a 45-degree angle to the skin and directed toward the object from either side. Radiographs can then be used for localization, and an incision made down to the tip of the needle closest to the object. Needles used in such a manner are especially helpful when fluoroscopy is available; when the extremity is rotated under fluoroscopy, the needles provide a three-dimensional effect useful for localizing, planning the overlying incision, and removing the object.
- 16. Localizing even a superficial foreign body can be difficult after the procedure has begun because of distortion by local anesthetic, edema, and tissue retraction. It can be especially difficult to localize deeply embedded foreign bodies owing to these conditions. One reported technique for localizing radiopaque foreign bodies uses hemoclips with silk sutures tied to them. After the clinician dissects down to where he or she thinks the foreign body is located, two or three hemoclips can be placed into the depths of the wound. On subsequent radiographs, the hemoclip located closest to the foreign body should be verified. This one should be left in place and the others removed. The incision and dissection pathway should then follow the silk suture down to the foreign body.
- 17. After removal of the foreign body, the wound should be irrigated with any remaining anesthetic. This irrigation should be followed by sterile saline pulsated from a syringe. Irrigation is helpful for removing any small fragments or debris that may be remaining. A jetted irrigation can be performed by attaching an 18-gauge needle to the syringe.
- 18. If a significant incision was made or a punch biopsy performed, reapproximate the skin with suture. Cover the wound with a sterile adhesive bandage and give the patient postprocedure instructions.
- 19. For a splinter under a nail, either a "V" can be cut in the distal nail to allow it to be reached and grasped, or a portion or all of the nail can be removed under a local block (see Chapter 28, Nail Plate, Nail Bed, and Nail Matrix Biopsy, and Chapter 29, Ingrown Toenails, for similar situations). Alternatively, a 27-gauge needle can be bent at its tip to form a hook, inserted under the nail, and used to hook the splinter and drag it out. If the entire splinter cannot be removed, at least the part of the nail covering any possible splinter fragments should be removed to allow for irrigation. Otherwise, because the subungual area is very close to the distal phalanx, any remaining fragments may increase the risk of infection and subsequent rapid spread to osteomyelitis.
- 20. Tetanus prophylaxis should be provided if appropriate.

#### **COMPLICATIONS**

- Trauma to local vital structures, such as nerves, arteries, veins, or tendons.
- Infection or bleeding.
- Scarring from the original wound, or from the incision and sutures that were necessary to locate the object and close the wound.
- Failure to remove the object, partially or completely. Again, for those objects that must be removed, needle localization under fluoroscopy may remain the final option. The patient should be informed if there was failure to remove the object, and this should be documented as well as any agreed-on plan for follow-up or removal.

#### **POSTPROCEDURE PATIENT EDUCATION**

After removal, a dull ache or stretching sensation in the area is normal for up to a day, especially if sutures were placed. Instruct the patient to watch for signs of infection. Itching is a normal sign of healing. The patient should follow up with the clinician in 2 days to check for infection (earlier if there are significant signs) and again in the appropriate number of days (7 days in most cases) for suture removal if sutures were placed. A topical antibiotic may be applied, and the dressing should remain over the wound for 48 hours. It should be changed if it gets wet during that time. After the first 48 hours, a dressing should be applied only if the wound continues to drain or if it could get dirty. After the first 48 hours, the wound may be washed with soap and water.

#### **CPT/BILLING CODES**

**NOTE:** As with all coding, the reimbursement is usually greater if there is a more descriptive code that includes the location, depth, and complexity (e.g., 23330 is approximately twice the RVUs as 10120, whereas 28192 is approximately four times that of 10120).

- 10120 Incision and removal of foreign body, subcutaneous tissues; simple
- 10121 Incision and removal of foreign body, subcutaneous tissues; complicated

For codes 20100 through 20103, exploration is defined as exploration and enlargement of the wound; extension of dissection (to determine penetration); débridement; removal of foreign body(s); or ligation or coagulation of minor subcutaneous and/or muscular blood vessel(s) of the subcutaneous tissue, muscle fascia, and/or muscle not requiring thoracotomy or laparotomy.

- 20100 Exploration of penetrating wound (separate procedure); neck
- 20101 Exploration of penetrating wound (separate procedure); chest
- 20102 Exploration of penetrating wound (separate procedure); abdomen/flank/back
- 20103 Exploration of penetrating wound (separate procedure); extremity
- 20520 Removal of foreign body in muscle or tendon sheath; simple
- 20525 Removal of foreign body in muscle or tendon sheath; deep or complicated
- 23330 Removal of foreign body, shoulder, subcutaneous tissue
- 24200 Removal of foreign body, upper arm or elbow area; subcutaneous tissue
- 24201 Removal of foreign body, upper arm or elbow area; deep (subfascial or intramuscular)
- 27086 Removal of foreign body, pelvis or hip; subcutaneous tissue
- 28190 Removal of foreign body, foot; subcutaneous tissue
- 28192 Removal of foreign body, foot; deep
- 28193 Removal of foreign body, foot; complicated

#### **ICD-9-CM DIAGNOSTIC CODES**

- 709.4 Foreign body granuloma of skin or subcutaneous tissue
- 729.6 Residual foreign body in subcutaneous or soft tissue
- 876.1 Foreign body back through open wound
- 879.3 Foreign body abdominal wall (anterior) through open wound
- 879.5 Foreign body abdominal wall (lateral) through open wound
- 880.13 Foreign body arm (upper) through open wound
- 882.1 Foreign body hand through open wound
- 884.1 Foreign body multiple arm through open wound
- 891.1 Foreign body calf, knee, leg through open wound
- 910.6 Foreign body face, neck or scalp superficial
- 910.7 Foreign body face, neck or scalp superficial infected
- 911.6 Foreign body abdominal wall, back, breast, buttock, chest, flank, groin, interscapular region, labia, penis, trunk, vagina or vulva superficial
- 911.7 Foreign body abdominal wall, back, breast, buttock, chest, flank, groin, interscapular region, labia, penis, trunk, vagina or vulva superficial infected
- 912.6 Foreign body arm, axilla superficial
- 912.7 Foreign body arm, axilla superficial infected
- 913.6 Foreign body forearm superficial
- 913.7 Foreign body forearm superficial infected
- 914.6 Foreign body hand superficial
- 914.7 Foreign body hand superficial infected
- 915.6 Foreign body finger superficial

- 915.7 Foreign body finger superficial infected
- 916.6 Foreign body calf, hip, knee or leg superficial
- 916.7 Foreign body calf, hip, knee or leg superficial infected
- 917.6 Foreign body foot or toe superficial
- 917.7 Foreign body foot or toe infected
- 919.6 Foreign body site NOS superficial
- 919.7 Foreign body site NOS superficial infected

# FUNGAL STUDIES: COLLECTION PROCEDURES AND TESTS

Dennis E. Babel

#### **DIAGNOSTIC METHODS**

The three basic methods used to diagnose fungal infections are direct microscopy (e.g., potassium hydroxide [KOH] method), fungal culture, and biopsy with histopathology.

#### **Direct Microscopy**

Early diagnosis of cutaneous mycoses can be made in the physician's office by direct microscopy of infected tissue or lesion exudate. A number of different clearing solutions can be applied to collected material to assist in direct microscopy. These agents help distribute the specimen so the clinician can more readily visualize any fungal structure. These solutions include simple saline, potassium or sodium hydroxide in various formulas and preparations, and various coloring agents.

#### **Fungal Culture**

The ultimate identification of fungal pathogens requires their isolation on fungal culture medium. This isolation can take place in the physician's office using fungal media such as Sabouraud's dextrose agar with cycloheximide (to inhibit fungal contaminants) and chloramphenicol (to inhibit bacterial contaminants). These are commercially available as Mycosel agar (BBL Microbiology Systems, Becton Dickinson Co., Cockeysville, Md), Mycobiotic agar (Difco Laboratories, Detroit, Mich), and Dermatophyte Test Medium (DTM), a presumptive color-change medium (Hardy Diagnostics, Santa Maria, Calif). Of the three listed, only DTM is a color-change medium for purposes of this chapter. Inoculation of an appropriate patient specimen on these agars should allow the growth only of the true causative fungal organism.

#### **Biopsy and Histopathology**

Biopsy specimens obtained from fungal lesions can reveal the in vivo morphology of the infectious agent as well as the host response to this invasive presence. The appropriately stained histopathology section can provide the clinician with proof of the presence of a fungal pathogen, clues to its identity, the extent of infection, and the patient's ability to respond to this invasion. Although this procedure might be considered the gold standard for the diagnosis of human mycoses, it is an invasive procedure, is somewhat costly, and is seldom required for the identification of cutaneous mycoses. A 3-mm punch biopsy is usually sufficient. The pathologist must be alerted if a fungal infection is considered in the differential.

#### **EOUIPMENT**

This list includes materials for collecting and examining specimens for cutaneous mycoses as described in the text. Not every item is needed for each collection method.

- Alcohol swabs
- $3 \times 3$  gauze squares
- Scalpel blade (no. 15)
- Toothbrush
- Cotton-tipped applicator
- Disposable biopsy punch (3 mm)
- Glass microscope slide  $(1 \times 3 \text{ in})$
- Coverglass (22 × 22 mm)
- 20% KOH with dimethyl sulfoxide solution
- Chlorazol black E solution
- Microscope with 10× and 40× objectives
- Fungal culture media in tubes, vials, or Petri dishes (see "Fungal Culture" section, earlier)

# CUTANEOUS MYCOSES SPECIMEN COLLECTION (FOR KOH PREPARATIONS AND FUNGAL CULTURES)

#### Hair

The most common mycoses of the hair are tinea capitis and tinea barbae (Fig. 19-1).

- Clean the area of alopecia thoroughly with alcohol to remove foreign debris and minimize bacterial contamination. This will not affect the viability of the fungi in any manner (Fig. 19-2).
- Collect a specimen with a scalpel, glass slide edge, new toothbrush, 3 × 3 gauze square, or cotton-tipped applicator (Fig. 19-3).
- Appropriate specimen could include black dots (hair stubs) or scalp scale from the area of alopecia. (Long hairs and hair clippings are unacceptable because they are seldom actually infected and are frequently contaminated with bacteria.)

#### Skin

Fungal infections of the skin include tinea corporis, tinea cruris, tinea pedis, tinea manuum, and candidiasis (Fig. 19-4).

 For annular or serpiginous lesions of the skin, clean the advancing lesional edge with alcohol and obtain the scaling epithelium (avoid collecting scale from the center or oldest portion of the

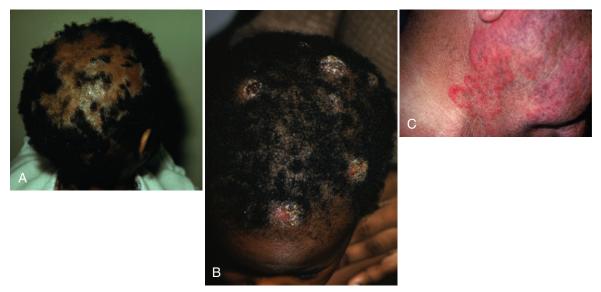

Figure 19-1 A, Black dot tinea capitis. B, Tinea capitis with kerion. C, Tinea barbae.

lesion because it is unlikely that the fungal pathogen is still present in that "healed" area). Scrape over the area firmly with the side of a scalpel blade to prevent bleeding. Loosened epithelial debris may be scraped directly onto a glass microscope slide for KOH examination and directly onto the fungal media surface for culture.

- For intertriginous mycoses, once again clean and collect material from the dry scaling edge. (Avoid any central, moist, macerated material because it is usually devoid of any viable fungi and is frequently contaminated with bacteria.)
- For vesicular mycoses of the skin, collect a portion of the vesicle roof by removing with a sterile scissors or scalpel blade. (Vesicular fluid and epithelium from the vesicle base are usually devoid of any fungi.)

#### Nail

Fungal infection of the nail (onychomycosis) is usually due to dermatophytes (tinea unguium) or Candida (Fig. 19-5).

- For distal subungual onychomycosis, trim back the nail to the leading edge of infection (edge closest to the proximal nail fold) and discard. Collect keratinaceous debris from beneath the remaining trimmed nail plate edge.
- For proximal subungual onychomycosis, reverse this process and collect material from the active edge closest to the distal end.
- For white superficial onychomycosis, clean and collect material by simply scraping the surface area of involvement.

NOTE: Less-than-ideal specimens are nail clippings and wholeremoved nail plate because the true fungal reservoir is actually the

Figure 19-2 Clean area with alcohol wipe.

nail bed (the exception being nail plate surface material from white superficial onychomycosis).

#### **TECHNIQUE FOR KOH PREPARATION**

See Figure 19-6A.

- 1. Place appropriate specimen (collected as previously described) on a clean glass microscope slide.
- 2. Add one drop of 20% KOH with dimethyl sulfoxide solution.\*
- 3. Add one drop of chlorazol black E solution.\*
- 4. Place a coverglass on top of the slide preparation and press down to eliminate air bubbles.
- 5. Blot excess solution from the finished slide preparation.
- 6. Place the preparation on the microscope stage and examine it with the *low-power* (10×) objective.
- 7. To enhance contrast, reduce the microscope illumination by lowering the condenser until epithelial cells are clearly visible.
- 8. *Screen* the slide preparation under low power (10×) for the presence of fungal structures, such as hyphae or yeast.
- 9. Examine suspect structures with the 40× setting (high-power dry objective) to confirm the presence of fungi (an oil immersion objective is *not* needed).
- 10. The observation of hyphae or budding yeast and pseudohyphae constitutes a "positive" KOH preparation for fungus.

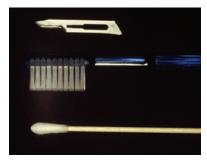

Figure 19-3 Tinea collection tools.

<sup>\*</sup>These solutions are commercially available (see the "Suppliers" section).

Figure 19-4 A, Tinea corporis (annular). B, Tinea cruris (serpiginous). C, Tinea pedis (vesicular). D, Tinea pedis (interdigital). E, Tinea manuum. F, Tinea faciei.

#### **Positive KOH**

- Dermatophyte (mold) causing tinea. Look for hyaline, septate filaments with diameters at least four times the diameter of an epithelial cell wall. This diameter should be very consistent (5 to 7 μm). This filament is linear and may course across a number of keratinocytes and occasionally branch (Fig. 19-6B–F).
- 2. Candida (yeast). Look for round to oval budding cells as well as "stretched out" budding cells (pseudohyphae; Fig. 19-6G).
- 3. Malassezia furfur (pityriasis versicolor). Look for short, hyaline, septate hyphae as well as round, clustered yeast cells ("spaghetti and meatballs"; see Fig. 19-6F).

#### **Common Errors in KOH Examinations**

- Not collecting specimen from the leading edge of infection.
- Not thoroughly cleaning the sample site with alcohol before sampling.

**Figure 19-5 A,** Distal subungual onychomycosis. **B,** Proximal subungual onychomycosis. **C,** White superficial onychomycosis. **D,** Candidal onychomycosis/paronychia.

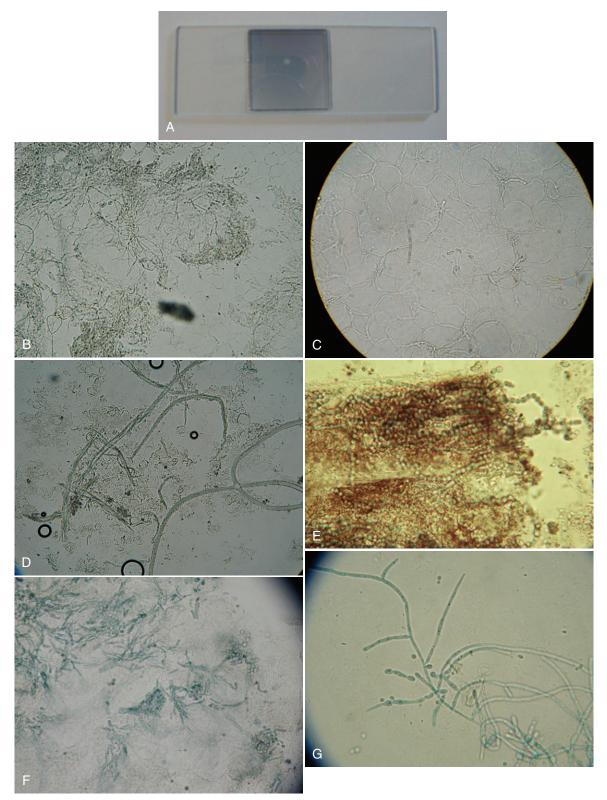

Figure 19-6 A, Glass slide KOH preparation. B, Positive KOH for hyphae (low power). C, Positive KOH for hyphae (high power). D, False-positive KOH preparation with foreign debris. E, Positive KOH for tinea capitis. F, Positive KOH for tinea versicolor ("spaghetti and meatballs"). G, Positive KOH for candidiasis.

- Not reducing the microscope light by racking down the microscope condenser to maximize contrast.
- Mistaking foreign matter (e.g., sock fibers, dirt, pollen) for fungal structures microscopically.
- Heating a KOH slide preparation to speed up the clearing process to the point where the chemical precipitates out. (Heating a slide preparation should not be necessary if using 20% KOH with dimethyl sulfoxide.)

# TECHNIQUE FOR A FUNGAL CULTURE (OFFICE PROCEDURE)

The greatest recovery of mycotic pathogens by fungal culture can be achieved through the inoculation of lesion material directly onto fungal media by the examining physician (Fig. 19-7). (Alternatively, the patient specimen that will be sent to an outside laboratory for inoculation should be packaged carefully and delivered in a timely fashion.)

- The patient specimen should be gently pressed onto the agar surface. Minimize "stabbing" and avoid "slashing" the agar because these techniques may lead to a premature drying out of the culture system.
- 2. Fungal cultures from most cutaneous specimens should be incubated at room temperature (22° C to 27° C) in a draft-free location and out of direct sunlight.
- 3. Presumptive pathogen media such as DTM, which rely on a color change from orange to red when a fungal pathogen is present, should be observed for the first 10 days. The development of a red agar color after this period should be considered a falsepositive result.

Figure 19-7 Fungal culture inoculation from tinea capitis with toothbrush.

### TECHNIQUE FOR BIOPSY FOR THE IDENTIFICATION OF CUTANEOUS MYCOSES

Biopsy specimens can be obtained for both the fungal culture and the histopathologic confirmation of the organism's presence in vivo.

- 1. A 3-mm punch biopsy obtained from the lesional edge is usually sufficient for both purposes (see Chapter 32, Skin Biopsy).
- The biopsy material should be divided longitudinally into two equal parts.
- 3. One biopsy portion should be placed into *formalin* and sent to the pathology laboratory with a request for "fungal stains."
- 4. The second biopsy portion should be placed in *sterile saline* and sent to the microbiology laboratory for "fungal culture."

# Incision and Drainage of an Abscess

Daniel J. Derksen

An abscess is a localized infection characterized by a collection of pus surrounded by inflamed tissue. When a sweat gland or hair follicle infection forms an abscess, it is called a furuncle, or boil. If multiple follicles are involved with abscesses, it is referred to as a carbuncle. Paronychia is an abscess that involves the nail. A felon is an abscess in the tuft of soft tissue in the distal phalanx of the finger. A hordeolum is an abscess on the evelid margin, whereas a chalazion is a chronic abscess of the eyelid itself in the meibomian glands beneath the tarsal plate (see Chapter 65, Chalazion and Hordeolum). Hidradenitis suppurativa is a chronic condition in the axilla and groin with recurrent abscess formation. Pilonidal abscesses are discussed in Chapter 109, Pilonidal Cyst and Abscess: Current Management: berianal abscesses in Chapter 107, Perianal Abscess Incision and Drainage; and Bartholin's abscesses in Chapter 131, Bartholin's Cyst and Abscess: Word Catheter Insertion, Marsupialization. For olecranon and prepatellar bursitis, see Chapter 192, Joint and Soft Tissue Aspiration and Injection (Arthrocentesis).

Most often, *Staphylococcus aureus* is the causative agent in abscesses, but some abscesses are due to *Streptococcus* species or a combination of microorganisms, including gram-negative and anaerobic bacteria. Perianal abscesses are usually caused by a mix of aerobic and anaerobic enteric organisms. Abscesses can occur in any location, but they are commonly found on the extremities, buttocks, and breast or in hair follicles.

A small abscess may respond to warm compresses or antibiotics and drain spontaneously. As the abscess enlarges, the inflammation, collection of pus, and walling off of the abscess cavity render such conservative treatments ineffectual. The treatment of choice for an abscess is incision and drainage (1&D), and if this treatment is done properly, antibiotics are usually unnecessary. (See precautions for the facial triangle in "Contraindications," later.) In a nonlactating woman, a breast abscess that is not subareolar is rare. If an abscess occurs away from the areola, it should prompt a biopsy in addition to I&D and raise the clinician's suspicion of a malignant tumor.

Patients with diabetes, debilitating disease, or compromised immunity should be observed closely after I&D of an abscess. Although usually not necessary, consider a culture obtained by aspiration or swab of the abscess cavity because the abscess may have been caused by unusual organisms in these compromised patients. The infection may also warrant the administration of antibiotics that cover *Staphylococcus* infection.

If an abscess recurs after incision and drainage, methicillinresistant S. aureus (MRSA) should be considered, a culture and sensitivity obtained, and the patient treated with appropriate antibiotics based on these results. Community-associated S. aureus is most often sensitive to clindamycin, trimethoprim/sulfamethoxazole, doxycycline, and rifampin. The frequency of MRSA skin and soft tissue infections has increased dramatically, and it is now the most common pathogen for these infections when patients present to the emergency department. Resistance changes rapidly and differs regionally. Initial treatment remains I&D, although some recommend treatment with one or more oral antibiotics based on culture and sensitivity.

#### **INDICATIONS**

A localized collection of pus that is tender and not spontaneously resolving. If the lesion is not "pointing" and localized, a trial of antibiotics may be indicated. However, antibiotics are usually inadequate once a collection of pus is present.

#### **CONTRAINDICATIONS**

Small, nonfluctuant facial furuncles without surrounding cellulitis should not be incised or drained if located within the triangle formed by the bridge of the nose and the corners of the mouth. These infections should be treated with antibiotics, with coverage for MRSA, and warm compresses because there is a risk of septic phlebitis with intracranial extension after I&D of a furuncle in this area. However, if the lesion is large and fluctuant, drainage is recommended, regardless of the site. In most instances, drainage alone is adequate, but in this area antibiotics are also recommended.

#### **EQUIPMENT**

- Local anesthetic (1% to 2% lidocaine), sodium bicarbonate 7.5%, or diphenhydramine (Benadryl) 50 mg/mL
- Syringe with 25- to 30-gauge needle, usually ½ to 1 inch, because only the skin over the abscess is anesthetized
- Possibly a cryosurgery unit or ethyl chloride for anesthesia (to avoid a needle poke)
- Alcohol or povidone-iodine (Betadine) wipe
- $4 \times 4$ —inch gauze
- No. 11 blade
- Curved hemostats
- Possibly iodoform gauze (¼- to ½-inch width, and up to 24 inches long depending on abscess size)
- Possibly culture materials
- Bandage scissors
- Dressing of choice

#### **TECHNIQUE**

Protective eyewear should be worn.

- 1. Prepare the abscess area with povidone-iodine or alcohol.
- Administer a field block with local anesthetic (see Chapter 8, Peripheral Nerve Blocks and Field Blocks) to allow an adequate

incision to be made. Avoid infiltration of the abscess cavity; rather, concentrate on anesthetizing the perimeter of the tissue around the abscess. Local anesthetics usually work poorly in the acidic milieu of an abscess. More anesthetic than usual may be needed to relieve pain. Alternatively, diphenhydramine 10 to 25 mg can be injected into the area for anesthesia. Dilute a 50-mg (1-mL) vial in a syringe with 4 mL of normal saline (Fig. 20-1A and B). Cryocautery can also be used to freeze the roof of the abscess. This can be performed with a nitrous oxide unit, liquid nitrogen, or ethyl chloride. The incision is then made through the cooled skin, which is now anesthetized.

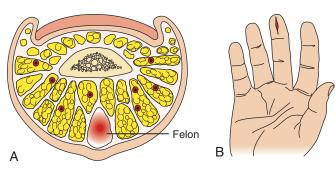

**EDITOR'S NOTE:** Nearly always, lidocaine will be adequate, but larger volumes may be needed.

3. Make a sufficiently wide incision with a pointed no. 11 blade to allow drainage of the abscess cavity and to prevent premature closure of the incision. If a large abscess is present, a 1-cm incision is usually large enough. Make the incision in the skin lines. Recurrence of the abscess is most often due to an inadequate

- incision and premature closure of the incision (Fig. 20-1C and D). Purulent material can "squirt out," especially if digital pressure is applied. Protective glasses and other precautions are suggested.
- 4. If a culture is obtained, it should be from the abscess cavity and not from the superficial skin over the abscess. Alternatively, the abscess cavity can be aspirated with a large-bore (18-gauge) needle before the incision is made. The aspirated contents can then be sent for the appropriate cultures in more complicated cases. This is rarely helpful in routine superficial abscesses.
- 5. Apply external pressure to express all pus (Fig. 20-1E). The abscess cavity should also be thoroughly explored with a sterile cotton-tipped applicator or with hemostats. Attempts should be made to break down any walled-off pockets or possible septa (Fig. 20-1F). If the lesion began as a cyst (e.g., sebaceous cyst), a small reusable dermal curette can be used to curette the cavity in the hope of removing all of the sac (Fig. 20-1G). Disposable curettes are often too sharp and may cause excessive damage. A residual sac can lead to a recurrent cyst. The cavity can be packed with

Figure 20-1 A, Large sebaceous cyst abscess of the back. B, Injecting local anesthetic (2% lidocaine with epinephrine). May augment with field block if desired. C, Incising abscess with no. I I blade. D, Purulent material is released from the lesion. E, Apply digital pressure to evacuate contents of the infected cyst. F, In the case of sebaceous cyst abscesses, the sac can often be grasped and removed using hemostats. It may be so necrotic in some lesions that it fragments, making removal more difficult. G, In cases where total removal of the cyst sac is uncertain, a reusable dermal curette can be used to scrape the cavity and remove any residual sac. H, lodoform gauze (1/4- or 1/2-inch, depending on size of cavity) is used to pack the wound open. Premature closure will lead to recurrence of the abscess. Suturing the wound closed is contraindicated. I, Insert the gauze using pickups without teeth. J, Apply antibiotic ointment over the tail of the iodoform gauze to prevent the outer dressing from sticking to it.

**Figure 20-2 A,** Anatomic cross-section of the distal phalanx, showing the numerous fascial septa and a felon. **B,** Incision of a felon. Incision should be in the longitudinal digital midline and should not cross a flexor crease.

- a Penrose drain or with packing material, preferably iodoform gauze. The length and width depend on abscess size. A small "tail" of gauze should be left protruding from the wound for drainage. Apply an ointment over the wound to prevent the gauze from sticking to the overlying dressing and being inadvertently removed when the dressing is changed (Fig. 20-1H through J).
- 6. Depending on the location and the size of the abscess, the gauze can be removed slowly over several weeks. Slowly advancing the packing will ensure that the wound does not close off too soon, and decreases the recurrence rate. The packing material can be changed daily, but it is painful and there is no real advantage to changing it. There may be some advantage to changing it after 5 to 7 days to reduce purulence and recheck the wound. For larger abscess cavities, leave the "wick" in for 4 weeks so that the abscess scars down from the inside. The patient can advance the drain every few days and cut off 2 inches at a time.
- 7. A sterile dressing can be applied over the area to collect discharge. This should be changed several times daily. Healing should progress from the inside out; that is, epithelialization of the abscess cavity should occur before healing of the incision site to minimize the chance of recurrence.
- 8. In patients with hidradenitis, I&D may traumatize the area and cause more long-term abscesses. However, the pain is usually so severe and acute with an abscess that I&D is necessary. Most patients with hidradenitis require long-term antibiotics, similar to patients with chronic acne. Some patients may require resection of all axillary or groin tissue involved.
- 9. A felon is an abscess in the distal tuft of the phalanx (Fig. 20-2A). A digital block serves best to anesthetize the area. Prepare with alcohol or povidone-iodine. Incise the abscess in the midline parallel with the digit (Fig. 20-2B). The large bilateral incisions of the past are now generally avoided. A small wick of iodoform gauze can be placed in the cavity for 24 hours. Many physicians use antibiotics in patients with felons to cover for S. aureus.

Usually I&D is sufficient to resolve an abscess. If cellulitis is present or the patient is at high risk for infection, an antibiotic can be used. It should cover *S. aureus*.

#### **COMPLICATIONS**

If the packing is tight in the abscess cavity, the pain can be sufficient to warrant use of acetaminophen or nonsteroidal anti-inflammatory drugs. Narcotics are rarely needed. I&D alone may provide sufficient pain relief from a tense abscess such that no pain medication is needed. Complications include the following:

- Recurrence
- Scar or keloid

- A failure to resolve, causing a cellulitis, or the progression to septicemia
- Formation of a fistula
- Osteomyelitis

An abscess in the palmar aspect of the hand can extend from superficial to deep tissue through the palmar fascia. Deep infection is suspected when the simple I&D fails to reduce the erythema, pain, pus, or swelling. More extensive surgical débridement, hospitalization, and intravenous antibiotics may be necessary in a patient with a deep palmar abscess, which is a surgical emergency.

A recurrent paronychia may require removal of the nail to resolve the infection (see Chapter 29, Ingrown Toenails, and Chapter 12, Approach to Various Skin Lesions). Also, consider treatment for *Candida* infection in fingernail cases.

#### POSTPROCEDURE PATIENT PREPARATION

Some patients can be taught to change their own packing, replace the dressings, and advance the drain. Other patients may require a family member or home nurse visits or may have to return to the office to have this done. Patients should be instructed to watch for signs of recurrence of the abscess and for evidence of further infection such as cellulitis, and to notify the clinician immediately if any of the following occur:

- Recollection of pus in the abscess
- Fever and chills
- Increased pain or redness
- Red streaks near the abscess
- Increased swelling in the area

Generally, bathing and frequent changes of the overlying dressing are encouraged.

#### **CPT/BILLING CODES**

Incision and drainage CPT codes vary by complexity and site.

10040 Acne surgery

10060 I&D one abscess

10061 I&D multiple/complex abscess

10080 I&D pilonidal cyst, simple

10081 I&D complicated pilonidal cyst

10140 I&D hematoma

10160 Aspirate abscess/cyst

10180 I&D complex/postoperative infection

19020 I&D deep abscess

21501 I&D deep, neck

23030 I&D deep, shoulder

23930 I&D deep, arm/elbow

23931 I&D infected olecranon bursa

25028 I&D deep, forearm

26010 I&D simple, abscess finger

26011 I&D complex, finger (felon)

26990 I&D deep, hip area

26991 I&D infected bursa, hip area

27301 I&D deep abscess/bursa knee

27603 I&D deep, leg/ankle

28001 I&D bursa, foot

28002 I&D deep, foot

30000 I&D drainage abscess or hematoma, nasal, internal approach

30020 I&D nasal septum (abscess hematoma)

40800 I&D vestibule mouth

40801 I&D complicated, mouth

41000 I&D lingual

41005 I&D sublingual (superficial)

#### 150 DERMATOLOGY

41006	I&D sublingual, deep
41800	I&D gums
45005	I&D submucosal rect abscess
46040	I&D perirectal abscess
46050	I&D superficial perianal abscess
46083	I&D hemorrhoid, external
54015	I&D deep, penis
54700	I&D epididymis
55000	Aspirate hydrocele
55100	I&D scrotal wall abscess
56405	I&D vulva
56420	I&D Bartholin's abscess
67700	I&D eyelid abscess
69000	I&D abscess pinna
69005	I&D abscess, pinna, complicated
69020	I&D ear canal abscess

#### **ICD-9-CM DIAGNOSTIC CODES**

For ICD-9-CM diagnostic codes, look under "abscess" for specific site

# INCISIONS: PLANNING THE DIRECTION OF THE INCISION

Julie M. Sicilia

Although generally considered minor procedures, skin incisions are invasive. They cause permanent changes in skin architecture and carry the potential for deleterious patient outcomes in terms of cosmesis and function. Skin incisions must be made with careful, thoughtful consideration and advance planning.

Several general issues should be addressed before deciding to perform an incision:

- Overall health status of the patient, including assessment of risk for:
  - Significant bleeding (bleeding dyscrasias, medications including herbs)
  - Potential for delayed wound healing (e.g., smoking, collagen vascular disease, diabetes, obesity, immunosuppression, steroid use, malnutrition, and peripheral vascular disease)
  - Allergy to any substance being used in conjunction with the procedure, including latex and the parabens preservatives in multiple-dose vials of anesthetics
- Need for antibiotic prophylaxis (e.g., dirty wounds, bites, infection, puncture, immunosuppression, diabetes)
- Ability of the patient or caregivers to properly care for the surgical wound postoperatively
- Expected benefits versus risks of the procedure

The physician must obtain an informed consent and ensure that the patient knows the basic complications of pain, bleeding, infection, recurrence, scarring, and distortion of the anatomy. The physician must always consider the patient as a whole being and not simply focus on "the lesion." Many pitfalls are avoidable if this is kept in mind.

Technical factors to be considered include the following:

- Avoidance of damage to any underlying vital structures
- Proper orientation of incision lines
- Correct design and size of the excision
- Avoidance of significant anatomic distortion

# AVOIDING DAMAGE TO UNDERLYING STRUCTURES

Simple full-thickness skin excisions performed with care usually do not pose a threat to underlying structures. The plane of removal should be at the junction of the adipose tissue and the dermis (Fig. 21-1). Nonetheless, familiarity with the anatomy of the proposed surgical site in regard to underlying nerves, vessels, tendons, bursae, and bony structures is essential. Of special concern are two nerves that lie superficially within the subdermal fat layer: the temporal branch of the facial nerve and the spinal accessory nerve (Figs. 21-2 and 21-3). Injury to the temporal branch of the facial nerve may cause inability to wrinkle the forehead and drooping of the eyebrow

on the affected side. Damage to the spinal accessory nerve can lead to loss of use of the trapezius muscle. When performing excisions in these regions, physicians should consider less invasive alternative methods for treating the particular lesion, if possible. If an incisional approach must be used, the patient should be advised of the potential complications.

#### **ORIENTATION OF THE INCISION**

Skin incisions and excisions must take into account static and dynamic skin tension to minimize scarring and maximize function. Langer's lines of minimal skin tension, in general, lie perpendicular to the long axis of underlying musculature and can usually be demonstrated by pinching together a local area of skin or by having the patient contract the muscles under that area. On the face, wrinkles form along these lines as a result of repeated contraction of the facial musculature. Linear incisions (e.g., for removal of underlying lesions such as lipomas or for incision and drainage) should be oriented parallel to wrinkle lines when possible (parallel to the lines of minimal skin tension). With an elliptical excision, in which a section of overlying skin is removed, the long axis of the ellipse should lie parallel to the lines of minimal skin tension. Standard depictions of Langer's lines (Fig. 21-4) assist in planning incisions, but lines of minimal tension must be evaluated on each patient individually before a procedure. For the face, the patient's simulating various facial expressions will aid in demonstrating natural wrinkle lines. It should also be noted that for certain elliptical excisions (especially on the face), the long axis of the excision may need to curve or angle instead of lying entirely in a straight line (Fig. 21-5). Planning incisions along lines of minimal tension decreases the forces on the wound that tend to pull it apart, thereby reducing scar potential. Certain areas, especially the deltoid and sternum, are invariably prone to experiencing transverse traction, with a subsequent wider scar and a higher propensity for keloid formation. Children also have an increased tendency to develop hypertrophic or keloid scars.

When lines of minimal tension are not apparent, even after the patient performs maneuvers to accentuate them, it may be helpful to first perform a circular excision, undermine the wound circumferentially, and then allow natural skin tension to orient the wound, usually into a more oval shape. At that point the resulting oval can be converted to an ellipse and the wound closed (Fig. 21-6).

Incisions across joint surfaces should be made transversely (or obliquely if necessary). Perpendicular lacerations or incisions across joint space lines have a tendency to contract, thus limiting range of motion. Chapter 17, Flaps and Plasties, includes a review of Z-plasty, an example of a situation in which a laceration extending across a joint is converted to a transverse wound to maximize joint function and minimize contracture.

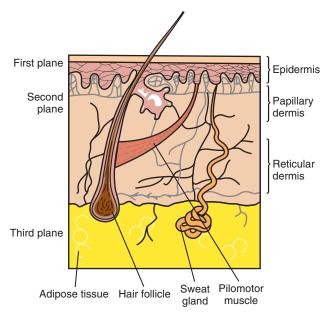

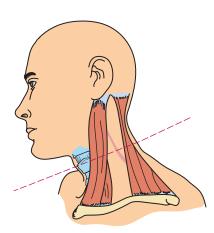

Figure 21-1 Skin anatomy.

**Figure 21-2** Temporal branch of facial nerve. The nerve lies superficially within a triangle created by a line extending from the tragus to the upper forehead wrinkle area and a line extending from the tragus to the lateral aspect of the eyebrow.

**Figure 21-4** Lines of minimal skin tension. **A,** Anterior body. **B,** Posterior view.

**Figure 21-6 A**, Creating a circular wound, with conversion to an ellipse. **B**, Creating an ellipse.

#### **DESIGN AND SIZE OF THE EXCISION**

Surgical marking pens should be used freely in designing incisions. Planning, measuring, and marking are essential steps toward an optimal result. The majority of skin excisions are elliptical in shape. The wound should be three times as long as it is wide (Fig. 21-7). A wound that is not long enough will create dog ears when repaired. Because alcohol will remove most marking pen inks, first use an alcohol wipe and anesthetize the wound, then mark and measure the planned excision, and finally anesthetize the surgical site. Next, prepare the site with povidone-iodine (Betadine), which will not remove the ink, and then drape the patient.

When incising with the scalpel, a no. 15 blade is used and should be held perpendicular to the skin or angled up to 15 degrees with the cutting edge angled away from the lesion (Fig. 21-8A and B). Remember that slight eversion during the repair is desirable (Fig. 21-8C). Slanting the blade in the opposite direction makes this difficult to accomplish. Remember to "build pyramids, not dig ditches"—when incising, the top of the blade should tilt slightly over the lesion, not away from it (Fig. 21-8D). Angling the blade more than 15 degrees creates a very thin "slice" of tissue on the remaining skin, which may necrose and lead to more scar formation.

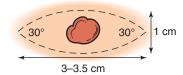

Figure 21-7 Creating an ellipse (proper dimensions).

Margins of normal tissue that should be removed vary depending on whether a lesion is benign or malignant, and, if malignant, the margins vary depending on the type of cancer (see Chapter 12, Approach to Various Skin Lesions). For benign lesions, the incision can be placed close to the lesion with only 1 or 2 mm of normal tissue excised. For melanomas, a 5-mm margin is needed if in situ, and a 1-cm margin is needed for any invasive melanoma less than 1 mm. If greater than 1 mm deep, consider referral.

For *basal cell carcinomas*, remove a 3- to 5-mm rim of normal tissue, and for squamous cell carcinomas, at least a 5-mm band of normal tissue around the lesion.

After the ellipse is made down to adipose, the tissue specimen is freed by cutting with the scalpel in the plane between dermis and adipose tissue. Using Adson pickups with teeth, grasp the end of the ellipse and dissect from one end to center. Then grasp the other end and do the same. This technique avoids the tendency to travel too deep within the excision (Fig. 21-9).

#### **AVOIDING DISTORTION OF SURFACE ANATOMY**

The physician should always attempt to estimate the change in surface anatomy that results from an excision. Pinching together the two sides of a planned ellipse assists in demonstrating whether a defect can be closed in a direct side-to-side fashion and if significant distortion of surrounding tissue will occur. The presternal, scalp, and pretibial regions can be potentially quite difficult to close after a skin excision, as can wider excisions in any location. Excisions necessitating removal of a significant amount of tissue on the forehead, upper lip, and around the eyes often cause distortion of facial appearance (Fig. 21-10). Proper planning creates excellent cosmetic results (Fig. 21-11).

# LACERATION AND INCISION REPAIR

Richard P. Usatine • Wendy C. Coates

Lacerations are a commonly seen problem in physicians' offices, urgent care centers, and hospital emergency departments. Lacerations can be repaired with sutures, wound closure tapes, staples (see Chapter 34, Skin Stapling), or tissue adhesive (see Chapter 37, Tissue Glues).

The goals of laceration and incision repair are as follows:

- Achieve hemostasis
- Prevent infection
- Preserve function
- Restore appearance
- Minimize patient discomfort

In repairing skin, it is helpful to understand the three phases of wound healing, which are listed in Box 22-1. Nonabsorbable skin sutures or staples are used to give the wound strength during the first two phases. After the nonabsorbable skin sutures are removed, wound closure tapes or previously placed deep absorbable sutures play an important role in the final phases of wound healing.

# **INDICATIONS**

- Lacerations that are open and less than 12 hours old (<24 hours old on the face)
- Some bite wounds in cosmetically important areas (close followup recommended)
- Repair of sites where a lesion has been surgically removed

#### **CONTRAINDICATIONS**

- Wounds more than 12 hours old (>24 hours old on the face)
- Animal and human bite wounds (exceptions: facial wounds, dog bite wounds)
- Puncture wounds

#### **EQUIPMENT**

- Surgical sterile preparation (Betadine, Hibiclens); alcohol swabs (not to be used inside the wound)
- Ruler in centimeters
- Irrigation device for contaminated wounds: 30-mL syringe with 18-gauge angiocatheter or commercially manufactured splash shield device (Fig. 22-1) and sterile saline
- Appropriate anesthetic, usually 1% or 2% lidocaine with or without epinephrine (see Chapter 4, Local Anesthesia)
- 1- to 10-mL syringe
- 27-gauge, 11/4-inch needle (small-gauge needles are preferred to administer anesthesia)
- Sterile drapes; fenestrated drape (applied over the lesion)

- 4 × 4 gauze sponges; sterile cotton applicators are useful for hemostasis
- Sterile pack containing 4½-inch needle holder; curved or straight iris scissors; one mosquito hemostat; suture scissors; Adson forceps with teeth; skin hook (optional)
- No. 15 blade for excisions with blade handle (single disposable unit also available)
- Appropriate suture (see Chapter 24, Laceration and Incision Repair: Suture Selection)
- Allis forceps for removal of deeper masses (optional)
- Skin marking pen (for excision, if wound revision is needed)
- Electrosurgical unit should be available for electrocoagulation
- Specimen jar (when lesions are being excised)
- Sterile gloves
- Protective mask with plastic shield for eyes or other types of personal protective equipment

#### PREPROCEDURE PATIENT PREPARATION

The patient should be informed of the nature of his or her laceration. If the laceration is in a cosmetically important area, consider offering the option of a plastic surgeon for the repair. Advise the patient about the risks of pain, bleeding, dehiscence, infection, and scarring. In the case of lesion removal, warn that it is not always possible to be sure that the entire lesion is removed, so it could recur. Inform the patient that most repairs cause some permanent scarring, although attempts will be made to optimize the appearance. Patients should apply sunscreen to the area for at least 6 months after repair to minimize scarring. Warn the patient of the risks of hyperpigmentation or hypopigmentation, hypertrophic scars, keloids, nerve damage, alopecia, and distortion of the original anatomy. It is advisable to have the patient sign a consent form (see the consent form available online at www.expertconsult.com).

# **Initial Assessment**

The initial evaluation *before anesthesia* should include a history of how the wound was sustained, factors that might impair healing, tetanus immunization history, and an assessment of peripheral neurovascular status.

For *elective excisions*, see Chapter 21, Incisions: Planning the Direction of the Incision, to plan the direction of the incision. If a traumatic laceration is to be repaired, see Table 22-1 for essentials of wound assessment. The clinician should consider the possibility of domestic violence in patients with traumatic wounds, especially if lacerations appear on the face or if multiple injuries of varying ages are noted.

In general, *antibiotics* are not needed for either wound or subacute bacterial endocarditis (SBE) prophylaxis for cutaneous procedures.

# Box 22-1. Three Phases of Wound Healing

Phase 1 (Initial Lag Phase, Days 0-5)

No gain in wound strength

Phase 2 (Fibroplasia Phase, Days 5-14)

Rapid increase in wound strength occurs

At 2 weeks, the wound has achieved only 7% of its final strength

Phase 3 (Final Maturation Phase, Day 14 until Healing Is Complete)

Further connective tissue remodeling Up to 80% of normal skin strength

For SBE prophylaxis guidelines, see Chapter 221, Antibiotic Prophylaxis. Consideration should be given to coverage for *Staphylococcus aureus* and methicillin-resistant *S. aureus* (MRSA) infection in several situations (Box 22-2).

The following are major goals for prescribing antibiotics before or after skin surgery:

- Prevention of a new wound infection
- Prevention of the spread of an existing local infection
- Treatment of an existing infection
- Prevention of bacterial endocarditis

The clinical decision-making process of whether or not to use antibiotics before or after skin surgery is complex. The physician must consider host factors, the anatomic location of the surgery, the sources that might contaminate the wound, and method of wound injury. Because this topic concerns wound repair after multiple types of trauma and elective procedures, the full complexity of the decision-making process is beyond the scope of this chapter. Box 22-2 lists the multiple factors to be considered when making a decision about antibiotic prophylaxis for skin procedures. See Chapter 222, Prevention and Treatment of Wound Infections.

The recommendations of the American Heart Association (AHA) for the *prevention of bacterial endocarditis* were last published in 2007. Endocarditis prophylaxis is not needed for incision or biopsy of surgically scrubbed skin. The 2007 guidelines state that antibiotic prophylaxis is recommended for procedures on infected skin and skin structures for patients with underlying cardiac conditions associated with the highest risk of adverse outcome from infective endocarditis. For individuals at highest risk for endocarditis (see

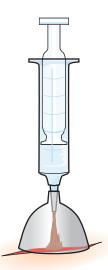

Figure 22-I Irrigation of a dirty wound using a syringe and plastic shield.

TABLE 22-1 Essentials	of Wound Assessment
Parameters	Factors to Consider
Mechanism of injury Dirty vs. clean Time since injury Foreign body	Sharp vs. blunt trauma, bite Outdoors vs. kitchen sink Suture up to 12 hr; 24 hr on face Explore and obtain radiograph for metal or glass
Functional examination Need for prophylactic antibiotics	Neurovascular, muscular, tendons If needed, give as soon as possible and cover Staphylococcus aureus; irrigate well

Chapter 221, Antibiotic Prophylaxis) who undergo a surgical procedure that involves infected skin or skin structures, it is reasonable that the therapeutic regimen administered for treatment of the infection contain an agent active against staphylococci and betahemolytic streptococci, such as an antistaphylococcal penicillin or a cephalosporin. Vancomycin or clindamycin may be administered to patients unable to tolerate a beta-lactam antibiotic or who are known or suspected to have an infection caused by MRSA.

Cummings and Del Beccaro (1995) performed a meta-analysis of randomized studies on the use of antibiotics to prevent infection of simple wounds. They concluded that there is no evidence in published trials that prophylactic antibiotics offer protection against infection of nonbite wounds in patients treated in emergency departments. Cummings (1994) also performed a meta-analysis of randomized trials for antibiotics to prevent infection in patients with dog-bite wounds and found that prophylactic antibiotics reduce the incidence of infection in these patients.

# Box 22-2. Possible Antibiotic Prophylaxis Situations or When to Consider Antibiotic Prophylaxis

#### **Coexisting Conditions**

Diabetes mellitus

Peripheral vascular disease

Elderly

Immunocompromised

Previous radiation to the site

Malnutrition (e.g., alcoholism, chemotherapy)

History of previous infection or slow healing

Chronic steroid use

Obesity

#### Locations

Increased bacteria

Axilla, mouth, anogenital areas

End-arterial locations (fingers, toes) with diseases of vascular compromise

Over joint spaces where there is a possibility of entering joint (e.g., metacarpophalangeal joints)

# Contamination

Dirty wounds, especially those sustained at farms, meatpacking plants, etc.

Less than optimal sterile technique (should be rare)

Deep puncture wounds

Bites (especially human and cat bites)

Presence of a retained foreign body

# Method of Wound Injury

Crush injury (10-fold increase in infection) with devitalized skin

Penetrating injury

Antibiotics have a role in the treatment of many established skin infections. However, most skin abscesses are better treated with incision and drainage rather than with antibiotics. For skin procedures, there is not a consensus on whether to give an antibiotic and the appropriate timing for its administration. Recommendations for timing before the procedure vary from 1 hour (which is typical timing for bacterial endocarditis prophylaxis) to within 30 minutes of the procedure. Although a single second dose 6 hours later was the standard in the past, it is no longer currently recommended for bacterial endocarditis prophylaxis but may be advocated for further treatment of the infection.

Controversy exists over which bite injuries should be treated with prophylactic antibiotics. Cat- and dog-bite injuries carry the risk of infection with Pasteurella multocida, and human-bite injuries carry the risk of infection with Eikenella corrodens and S. aureus. Based on the microbiology of these wounds, amoxicillin/clavulanate provides good prophylactic coverage for the bacteria affecting most bite injuries. Alternatives include second-generation cephalosporins or clindamycin with a fluoroquinolone.

The best method for prevention of wound infections is to clean and irrigate traumatic wounds well, rather than relying on prophylactic antibiotics. The physician needs to weigh the benefits and the risks of antibiotic use based on the individual patient and the circumstances of the wound repair or skin surgery. The factors listed in Box 22-2 and the references at the end of this chapter should provide guidance for the physician making decisions about antibiotic prophylaxis for skin surgery.

# Local Anesthesia

In traumatic wounds, neurovascular integrity should be assessed before administration of anesthesia. The wound should then be fully anesthetized to allow for painless examination of the tissue damage, thorough irrigation, and adequate closure. Many wounds can be adequately anesthetized with 1% or 2% lidocaine. Consider using lidocaine with epinephrine to provide increased hemostasis if there are no contraindications to epinephrine in the patient, the location of the wound, or the wound itself. (See Chapter 4, Local Anesthesia, and Chapter 8, Peripheral Nerve Blocks and Field Blocks.) Topical anesthetics are effective for wounds that do not involve mucosal surfaces. A combination of lidocaine, epinephrine, and tetracaine (LET) applied with a saturated cotton ball or as a gel formulation directly into the wound provides adequate anesthesia for many wounds.

Perform the following to minimize the pain of injecting local anesthetic:

- Use a small-gauge needle (27 gauge or smaller)
- Inject slowly
- Inject directly into the dermis through the open wound (not through intact skin)
- Warm anesthetic to body temperature (optional)
- Buffer the anesthetic with sodium bicarbonate (10 mL to 1 mL) (optional)

# **Wound Preparation**

After the initial assessment and administration of local or regional anesthetic, and antibiotics if indicated, wounds should be inspected thoroughly for foreign bodies, deep tissue layer damage, and injury to nerve, vessel, or tendon. A radiograph should be obtained to look for retained glass or metal in wounds sustained with broken glass or metal. Complex wounds or those in cosmetically important areas should be closed by a practitioner with the appropriate expertise.

#### Cleansing

After the wound is anesthetized, cleansing of a traumatic wound should be performed by irrigation with normal saline at approxi-

mately 15 psi of pressure. This can be accomplished by attaching an 18-gauge angiocatheter or a commercially available splash shield to a 30-mL syringe (see Fig. 22-1). At least 200 mL of irrigation is recommended. Moscati and associates (2007) performed a multicenter comparison of tap water versus sterile saline for wound irrigation showing equivalent rates of wound infection in immunocompetent patients. The tap water group irrigated their own wounds under the water tap for a minimum of 2 minutes after they had the wound anesthetized. Higher-risk wounds were excluded from the study, suggesting that tap water is a reasonable cleansing alternative only in low-risk lacerations. Chemical compounds such as hexachlorophene (pHisoHex), chlorhexidine gluconate (Hibiclens), or povidone-iodine (Betadine) should not be used inside wounds but may be applied to external, intact skin if desired. Greasy contaminants can be removed with any petroleum-based product, such as bacitracin ointment. To prevent a "road rash" tattoo, wrap petrolatum gauze around the fingers and wipe off the asphalt and other foreign material embedded in the skin after anesthesia.

For elective excisions, irrigation before closure is not generally needed. If there was a ruptured cyst or if the excisional area was open a considerable time, or if there was concern about contamination, irrigation with 10 mL of saline two or three times may be performed.

#### **Débridement**

After the cleansing process, wounds should be examined for devitalized tissue that needs removal or débridement. This débridement may convert a jagged, contaminated wound into a clean surgical one and can be accomplished with a scalpel or sharp tissue scissors (Fig. 22-2). Preserve as much tissue as possible in case future scar revision is necessary. After débridement, wound edges should be held together to see if they are under any tension. Wounds under significant tension are best repaired by a two-layer closure. In dirty wounds, however, this may increase the incidence of infection.

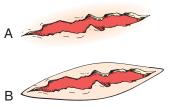

#### **Undermining**

Undermining can significantly reduce skin tension when there is a gap to be closed (Fig. 22-3). Undermining may increase the risk of infection and thus should be avoided in dirty wounds. Extreme care is also needed when undermining around vital structures. Approximately one third to one half of the undermined tissue is freed up to be brought into the defect. Undermine bilaterally as far back as the wound is wide.

## **TECHNIQUE**

Ideally, four principles should be incorporated in the process of closing any wound:

- Control all bleeding before closure. This can be accomplished by applying direct pressure for at least 5 minutes, adding epinephrine to the local anesthetic when appropriate, using electrocoagulation, or tying off bleeders with absorbable sutures.
- 2. Eliminate "dead space" where tissue fluid and blood can accumulate (Fig. 22-4).

**Figure 22-2** Débridement. **A**, Irregular jagged wound. **B**, Excise a jagged wound or crush injury to create a more readily reparable wound.

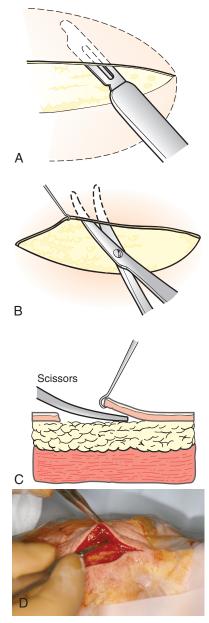

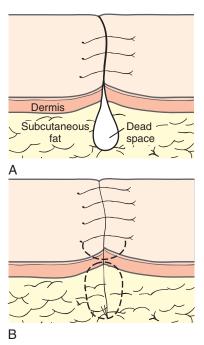

Figure 22-3 When skin margins approximate with tension, this can be relieved by undermining the margins through the use of a blade (A) or scissors (B and C). The usual plane is at the dermal—adipose junction. Undermine twice as far back as the wound is wide, if possible. The proper level of undermining to mobilize the skin is shown (D). (D, Courtesy of The Medical Procedures Center, PC, Midland, Mich, John L. Pfenninger, MD.)

- 3. Accurately approximate tissue layers to each other. Scars are most visible when shadows are created by depressed or elevated tissue. Also be sure that anatomic areas match on each side in critical areas such as the vermilion border of the lip.
- 4. Approximate the wound with minimal skin tension. If there will be significant tension, undermining and deep inverted buried sutures are used to decrease the tension on the skin margin. Ideally, when the repair is completed the wound will be tented up slightly.

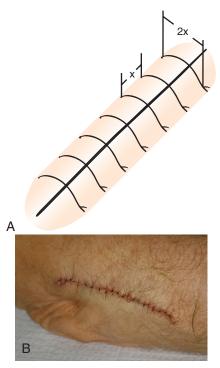

Lacerations and incisions are approximated using a variety of techniques:

• Simple interrupted suture (Fig. 22-5). On completion, the skin margins should be slightly everted (Fig. 22-6). The needle should enter the skin surface at a 90-degree angle (Fig. 22-7). The stitch

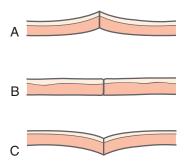

**Figure 22-4** Closing the dead space. **A,** Improper closure with dead space not closed. **B,** Proper closure with dead space closed by deep sutures.

should be as wide as it is deep. The suture on both sides of the wound should be of equal distance from the wound margin and of equal depth. The final shape should appear like an Erlenmeyer flask (Fig. 22-8). As a general rule, these sutures need to be no closer than 2 mm in a fine plastic closure and can be substantially farther apart in other types of closures. The distance between sutures should equal half the total distance of the sutures across

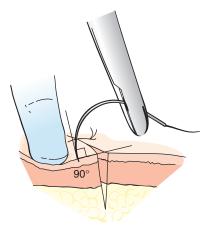

**Figure 22-5** Simple interrupted suture. **A,** Proper spacing. **B,** Interrupted sutures after excision of a basal cell carcinoma of the elbow. (**B,** Courtesy of The Medical Procedures Center, PC, Midland, Mich, John L. Pfenninger, MD.)

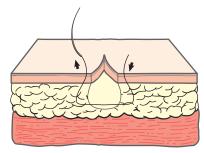

**Figure 22-6** Wound margin appearance after closure. **A,** Proper eversion of the skin edges on closure ("build pyramids, not ditches"). **B,** Acceptable, but not optimal, closure. **C,** Improper closure because healing will lead to further contraction and scar depression.

the incision. Avoid tying the *knots* too tight. The knots should be lined up on one side of the wound. The finer the suture, the closer the stitches need to be. See Chapter 23, Laceration and Incision Repair: Needle Selection, and Chapter 24, Laceration and Incision Repair: Suture Selection, for needle and suture selection, respectively. See Chapter 25, Laceration and Incision Repair: Suture Tying, for tying techniques.

- Simple running stitch (Fig. 22-9). The advantages of the simple running stitch in sterile wounds under little or no tension are that it is quick and distributes tension evenly and provides excellent cosmetic results. Because there is an increased risk of contamination in traumatic lacerations, the simple running stitch is less desirable in these wounds. In case of infection, the entire wound closure would need to be removed. If there is significant gaping of the wound, interrupted suture methods should be used. The relative disadvantage is that the entire stitch must be removed at once; with interrupted techniques, some sutures may be removed early for better cosmesis whereas a few remaining ones can be left for prevention of dehiscence and removed at a later date. This stitch is ideal in the scalp and is the one generally used for episiotomy repairs.
- Deep suture with inverted knot or "buried stitch" (Fig. 22-10). Deeper wounds or wounds under tension are best closed by providing structural support and not relying solely on nonabsorbable superficial sutures. Well-placed, deep absorbable sutures can do much to aid in closing a wound, removing tension from the superficial skin sutures, and decreasing scarring by providing increased wound support long after the epidermal sutures have been removed. The inverted knot technique places the bulk of the

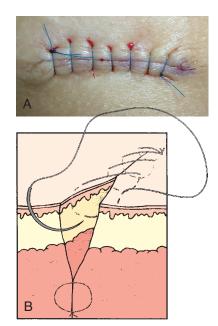

**Figure 22-7** Needle should enter the skin surface at a 90-degree angle. (Revised from Moy R: Suturing techniques. In Usatine RP, Moy RL, Tobinick EL, Siegel DM [eds]: Skin Surgery: A Practical Guide. St. Louis, Mosby, 1998, pp 88–100.)

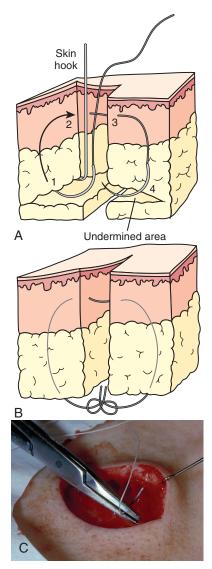

**Figure 22-8** Use the Erlenmeyer flask–shaped pathway to promote eversion of skin edges. (Revised from Moy R: Suturing techniques. In Usatine RP, Moy RL, Tobinick EL, Siegel DM [eds]: Skin Surgery: A Practical Guide. St. Louis, Mosby, 1998, pp 88–100.)

knot as far below the skin margins as possible to avoid suture spitting (migration of deep sutures to the skin surface). It also keeps the ends of the cut suture from protruding through the wound margin. To start the stitch, begin at the bottom of the wound (in the undermined area if undermining was used) and come up usually just below the epidermal–dermal junction (remember, "Bottoms up!") to start. Go straight across the incision; enter at the same level at the opposite side; then go down to the base at the same depth as the contralateral side and tie. Care should be taken to achieve symmetry of depth and width on both sides of the laceration. After the appropriate number of deep inverted sutures is placed to approximate the skin margins, the surface (skin) is then fully closed with the closure of choice (nonabsorbable suture, wound closure tapes, or tissue adhesive).

Vertical mattress suture (Fig. 22-11). This suture promotes eversion
of the skin edges. It is useful when the natural tendency of loose
skin is to create inversion of the wound margins, which is to be
avoided. A good example is the loose, flabby skin under the
triceps muscle and thin skin in older people. The stitch is also
appropriate when the skin is very thin and interrupted sutures
have a tendency to pull through.

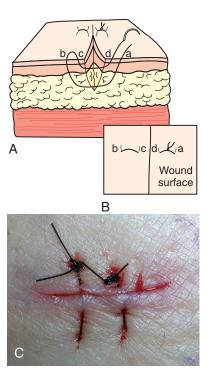

**Figure 22-9** Running stitch. **A,** This is a good stitch to use if there is no tension on the wound or after deep stitches were already placed with good approximation of the wound edges. **B,** Always keep the depth of the suture placement the same on each side. (**A,** Courtesy of Richard P. Usatine, MD, San Antonio, Tex; **B,** From Moy R: Suturing techniques. In Usatine RP, Moy RL, Tobinick EL, Siegel DM [eds]: Skin Surgery: A Practical Guide. St. Louis, Mosby, 1998, pp 88–100.)

**Figure 22-10** Deep stitch with absorbable suture material. **A,** Needle should enter deep in the skin below the dermis where the undermining was accomplished (1) and exit in the upper dermis (2). The needle enters in the upper dermis (3) and exits below the dermis where the undermining was accomplished (4). **B,** The deep inverted buried stitch is tied at the bottom of the wound to avoid having the knot stick out of the incision. **C,** Placing the deep stitch. (From Moy R: Suturing techniques. In Usatine RP, Moy RL, Tobinick EL, and Siegel DM [eds]: Skin Surgery: A Practical Guide, St Louis, Mosby, 1998, pp 88–100.)

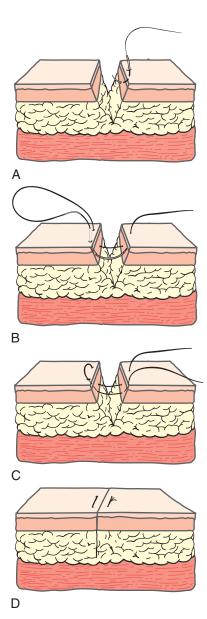

- Horizontal mattress suture (Fig. 22-12). This suture is helpful in
  wounds under a moderate amount of tension and also promotes
  wound edge eversion. It is especially useful on palms or soles and
  in patients who are poor candidates for deep sutures because of
  susceptibility to wound infections.
- Subcuticular running suture (Fig. 22-13). This suture is used to close linear wounds that are not under much tension; it yields an excellent cosmetic result. The two ends can be tied over the wound, or a knot can be placed at each end to prevent slippage. The ends of the suture do not necessarily need to be tied; taping under slight tension preserves approximation. Usually a polypropylene-coated nylon works best. Steri-Strips, tapes, or tissue glue can be used to supplement this type of stitch. Special care must be taken to avoid pressure on the wound because this stitch

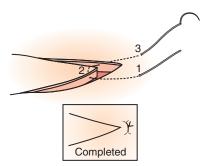

**Figure 22-11** Vertical mattress suture. **A,** Cross-section. **B,** Overhead view. Begin at a, and go under skin to b. Come out, go in at c, and exit at d. **C,** Photograph of two vertical mattress sutures used to obtain wound eversion. (Courtesy of Richard P. Usatine, MD, San Antonio, Tex.)

- separates easily. Applying Tegaderm or similar protective sheets provides added protection and strength.
- Three-point or half-buried mattress suture, also known as the "corner stitch" (Fig. 22-14). This suture technique is designed to permit closure of the acute corner tip of a laceration or of certain incisional techniques (e.g., Burow's triangle) without impairing blood flow to the tip. It is an intradermal stitch in which the needle is inserted initially into the intact skin on the nonflap portion of the wound and passed through the skin at the mid-dermis level; at the same level, the suture is then passed transversely through the tip of the flap, returned on the opposite side of the wound, and brought through the skin, paralleling the point of entrance. The suture is tied by drawing the tip snugly into place in good approximation. Care should be taken not to have the knot tied over the point of the flap (caused by having the needle insertion starting too far laterally). This same approach can be used in closing a stellate laceration, drawing the tips together in a pursestring fashion. Repair of a "T" laceration also uses this technique (Fig. 22-15).
- Repair of a dog ear or management of excess tissue can be performed as shown in Figure 22-16 (see Chapter 17, Flaps and Plasties). Figure 22-17 reviews the steps in the repair of a C-flap laceration.

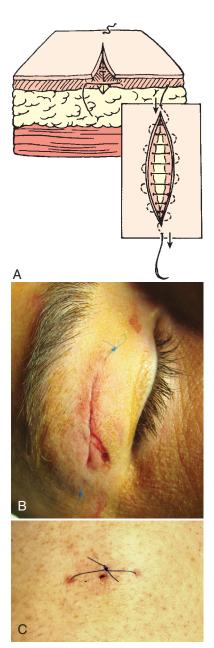

NOTE: In one study, otherwise healthy children with facial lacerations were randomized to repair using fast-absorbing catgut or nylon suture (Luck and colleagues, 2008). There were no significant differences in the rates of infection, wound dehiscence, keloid formation, and parental satisfaction between the absorbable catgut and the nylon suture. Fast-absorbing catgut suture is not as easy to work with as nylon but does have the advantage of not requiring suture removal in children who may be very fearful of the suture removal process.

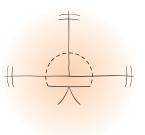

**Figure 22-12** Horizontal mattress suture. **A,** Needle is passed 0.5 to I cm away from wound edge deeply into the wound. **B,** Needle is passed through the opposite side and reenters the wound parallel to the initial suture. **C,** Reenter the skin perpendicularly to provide some eversion of the wound edges. Enter and exit both the wound and skin at the same depth; otherwise, "buckling" and irregularities occur in the wound margin. **D,** Suture is then tied as shown.

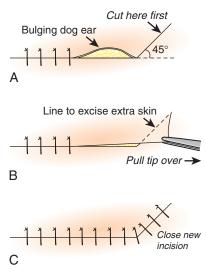

**Figure 22-14** Three-point or half-buried mattress suture to repair a V-flap laceration.

**Figure 22-13** Subcuticular running suture. **A,** Graphic depiction. **B,** Prolene was used to repair this eyebrow laceration. **Figure 22-16** Dog-ear repair. **A,** Note site of initial incision of bulging dog ear. **B,** Pull the tip over and excise. **C,** Close the new incision for skin to lie flat.

# **Wound Closure Tapes and Strips**

Wound closure tapes (Fig. 22-18) may be used alone for small, superficial wounds (especially in young children). When these tapes suffice to close a wound, they are easily placed without physical or psychological trauma to the patient. Wounds closed with tape are

more resistant to infection than are sutured wounds. Tape cannot provide adequate skin edge eversion or deep tissue approximation when used alone. Thus tape is most commonly used as an adjunct to sutures or staples. Tape can help reinforce wounds closed subcuticularly or with conventional suturing techniques. Adhesion is enhanced by the application of a sticky substance to the skin surface. Traditionally, tincture of benzoin has been used for this purpose, but a preparation containing gum mastic (Mastisol) has been shown to provide stronger adhesion. Wound closure tapes are especially helpful after suture removal to prevent dehiscence and may be left on until they fall off. Patients may shower with them on after the initial 24 hours.

The proper method of applying the strips is to apply benzoin or Mastisol over the entire area, then place the strips in a parallel fashion without overlapping and without "tacking" strips (see Fig. 22-18).

#### Tissue Adhesive

Tissue adhesives may be used to close certain wounds that are not under significant tension and are not at risk for infection (see Chapter 37, Tissue Glues).

# **Delayed Primary Closure (Tertiary Intention)**

Primary closure is defined by the use of sutures, tapes, or adhesives to close the wound at the time of initial surgery or evaluation. Healing by secondary intention occurs when no attempt is made to close the wound and the wound granulates in on its own. This method is used after a simple shave biopsy, in grossly contaminated or infected wounds, or in wounds that present far too late to consider closure. Delayed primary closure is healing by tertiary intention.

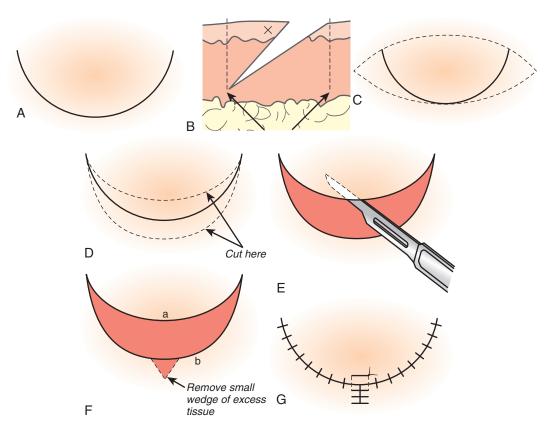

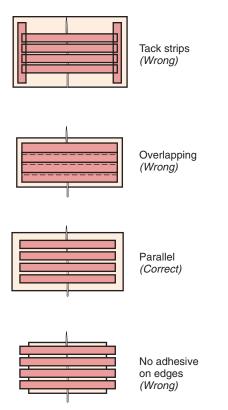

Figure 22-17 C-flap repair. **A,** Laceration. **B,** The problem: The point X is often very thin and may necrose. Even if it does not, contracture will occur after healing and the slim margin along the X will be depressed, causing a more visible scar. **C,** If small enough, convert the wound to an ellipse for easier repair. **D,** Alternatively, excise the angled margins of skin to obtain "square" borders. **E,** Undermine. **F,** Close with interrupted sutures. Because side a is smaller than side b, a small wedge of tissue may need to be removed. **G,** Complete closure.

**Figure 22-18** The red rectangles illustrate where Mastisol was applied to the skin.

Delayed primary closure is used for wounds that are greater than 12 hours old (24 hours for facial lacerations) but would safely benefit from closure in a few days. Repairing them immediately could increase the chance of infection. After anesthetizing, evaluating, and irrigating the wound, insert a small piece of petrolatum gauze between the wound edges and place the patient on an antibiotic, such as cephalexin, for 5 days. On the third day, the patient should return for definitive repair. The wound is then anesthetized, reirrigated, and closed primarily with nonabsorbable sutures (i.e., no deep sutures because they increase the chance of infection).

See Box 22-3 for a summary of key points for suture repair (also included in Appendix H, Pearls of Practice).

# POSSIBLE COMPLICATIONS OF LACERATION REPAIR

The following complications may occur within the first 2 weeks\*:

- Infection
- Pain
- Bleeding
- Dehiscence
- Hematoma
- Bruising and swelling
- Suture spitting

Prolonged or permanent complications may include the following:

- Scarring
- Hypertrophic scars
- Keloid formation

# Box 22-3. Pearls of Suturing

Use 27- to 30-gauge needle for anesthesia; slow injection; warm solution.

Use 1% to 2% lidocaine (epinephrine is helpful to achieve hemostasis). Avoid epinephrine or use with extreme care in fingers, toes, nose, ears, and penis. Do not use epinephrine in digital blocks.

Make elliptical excision at least three times as long as wide. Follow Langer's lines.

Undermine. Undermine. Double the width of the wound on each side.

Eliminate all dead space.

Use deep inverted buried absorbable sutures to reduce skin tension ("bottoms up").

Evert skin edges slightly ("build pyramids, not ditches"). Inversion of wound edges results in 300% increase in time for epithelial bridging.

Place interrupted sutures half as far apart as they are across. The more tension, the more sutures needed. Follow the Erlenmeyer flask shape. The finer the suture, the more sutures needed, but the less scarring.

Edema occurs after closure. Only approximate tissues; do not strangulate.

Begin gentle washing of wound after 12 to 24 hours; if Steri-Strips or tissue glues are not used, apply an ointment to keep the wound moist to speed healing.

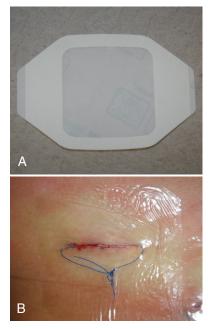

Apply Steri-Strips after suture removal.

- Hyperpigmentation
- Hypopigmentation
- Nerve damage
- Imperfect cosmetic alignment (e.g., the vermilion border)
- Suture spitting
- Recurrence of an incompletely excised lesion

#### POSTPROCEDURE PATIENT EDUCATION

Most wounds are best protected with some sort of dressing during the first 24 to 48 hours after closure. Continued slight oozing of blood might be expected. For hemostasis, a pressure dressing should be applied. This could be folded gauze over a sterile ointment with tape over it or a nonstick type of gauze dressing covered with gauze and tape. Trade names for nonstick dressings include Xeroform, Adaptic, and Telfa. For the extremities, the use of a self-adherent wrap like Coban, CoFlex, and others provides a good pressure dressing to hold things in place. If on the lower extremities, elevation helps for 24 hours. Ice over the area for a few hours will reduce pain, swelling, and bleeding. It is not usually necessary to keep a wound completely dry after 24 hours. Therefore, patients may shower after 24 hours and redress the wound after gently drying it. Moist healing (application of some type of ointment after gentle washing twice daily) aids in quicker healing. Although it has been traditional to use antibiotic ointments for dressings postsurgically, Smack and colleagues (1996) determined that clean wounds heal just as well when white petrolatum is applied. Neomycin and bacitracin are frequent contact allergens. Alternatively, Tegaderm or Opsite (transparent, self-adherent, plastic wrap-type dressings that "breathe out" but do not let anything in) can be applied and left in place until the sutures are removed (Fig. 22-19). If bleeding occurs, the patient can replace the dressing after 24 to 48 hours because it is available over-the-counter. In addition to providing the optimal moist healing environment, these dressings provide added support to the sutured closure.

**Figure 22-20** Suture removal. **A**, Cut where the suture enters the skin. **B**, Cutting suture near knot leaves length of suture that is "dirty" and pulled into the tissue. **C**, Pull the forceps over the wound, which approximates wound edges. **D**, Pulling suture out this way tends to pull wound edges apart. Also, note dirty length of suture being pulled through wound.

**Figure 22-21** Suture removal scissors. (Courtesy of The Medical Procedures Center, PC, Midland, Mich, John L. Pfenninger, MD.)

Suggestions for the timing for skin suture removal are listed in Table 22-2. See Figure 22-20 for proper suture removal techniques. Using suture scissors makes removal much easier (Fig. 22-21). Because scarring increases the longer the sutures remain in place, consider removing them a few days early and applying a tissue adhesive (see Chapter 37, Tissue Glues). Early removal is possible only if there is little to no tension on the wound. Even when sutures are removed at the usual times, tissue glues help keep the wound edges opposed. The high cost of tissue glues is one barrier to this approach. IsoDent (Ellman Corp., Hewlett, NY) is markedly less expensive and works as well as the more common glues. Adhesive strips or another self-adherent transparent dressing can also be used.

Wounds on the face or scalp may be dressed with a thin layer of antibiotic ointment or petrolatum in lieu of a mechanical dressing. It is best to cover these wounds at night to avoid drying. Instruct patients to return if there are signs of wound infection, including erythema, pus, lymphangitis, or fever. A routine wound check is unnecessary for patients who understand the importance of monitoring wounds for signs of infection. An instructional handout can be given (see the patient education form available online at www.expertconsult.com).

#### **CONCURRENT TREATMENT**

# **Tetanus Prophylaxis**

Table 22-3 is based on the current Centers for Disease Control and Prevention recommendations for tetanus prophylaxis in wound management.

# **Analgesic Medication**

Analgesic medication may need to be administered for a few days depending on the extent of the trauma, the pain threshold of the

**TABLE 22-3** Centers for Disease Control and Prevention Recommendations for Tetanus Prophylaxis in Wound Management

	Clean, Wound	Minor ds	All O	
Vaccination history	Td <sup>†</sup>	TIG	Td	TIG
Unknown or less than three doses	Yes	No	Yes	Yes
Three or more doses <sup>‡</sup>	No§	No	No <sup>  </sup>	No

TIG, tetanus immune globulin.

\*Such as, but not limited to, wounds contaminated with dirt, feces, soil, and saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite.

<sup>†</sup>For children younger than 7 years of age, DTaP or DTP (DT, if pertussis vaccine is contraindicated) is preferred to tetanus toxoid alone. For patients older than 7 years of age, Td is preferred to tetanus toxoid alone.

<sup>‡</sup>If only three doses of fluid toxoid have been received, a fourth dose of toxoid, preferably an absorbed toxoid, should be given.

§Yes, if more than 10 years since last dose.

Yes, if more than 5 years since last dose. (More frequent boosters are not needed and can accentuate side effects.)

From Diphtheria, tetanus, and pertussis: Recommendations for vaccine use and other preventive measures: Recommendations of the Immunization Practices Advisory Committee (ACIP). MMWR Recomm Rep 40(RR-10):1–28, 1991.

patient, and the concerns of the family. For most patients, over-thecounter medications are sufficient, but in selected patients prescription narcotics may be indicated. If antibiotics are needed, refer to earlier discussion under Initial Assessment.

#### CONCLUSION

In the treatment of lacerations, careful inspection, adequate irrigation, skilled closure, and appropriate wound care can produce the best functional and cosmetic results. The principles and steps covered in this chapter show how lacerations can be repaired with maximal skill and minimal discomfort to the patient. More advanced skills and knowledge can be developed through experience and by reading Chapter 17, Flaps and Plasties, and the sources listed in the bibliography.

#### **PATIENT EDUCATION GUIDES**

See the patient education and consent forms available online at www.expertconsult.com.

# CPT/BILLING CODES AND ICD-9-CM DIAGNOSTIC CODES

Coding and billing become very complex for laceration repair and excisions. Important factors to list for billing personnel are as follows:

- Location
- Size of lesion
- Length of closure or excision
- Simple or intermediate repair (intermediate includes either undermining or placement of deep buried sutures)
- Benign or malignant status
- Whether a true skin lesion or subcutaneous tumor or deep tumor (e.g., lipoma) was excised
- Method of removal (shave, excision, destruction)

With an excision, when charging for the size of the lesion, also include the width of the margins. For example, if a basal cell carcinoma that has a diameter of 1 cm is being excised, there should be 0.3-cm free margins. The size charged for the excision would be 1.6 cm. Suture removal is included in the initial charge if the original sutures were placed by the same group of physicians. Suture removal can be billed if performed by an unassociated physician or group. Anesthetic, materials, and supplies are customarily also included in the reimbursement fees. If a lesion is excised and repaired in a simple fashion (no undermining, deep sutures, flaps, or plasties), the fee for excision then includes local anesthesia, repair, any interval care for 10 days, and suture removal. If an intermediate repair is done with an excision, two codes should be charged (the excision and the repair).

For CPT/billing codes, see Table 22-4. For ICD-9-CM diagnostic codes, see Appendix G. For specific skin lesion sites, and to code out lacerations, go to the ICD-9 manual and look under wounds for the specific site: Wound, open (by cutting or piercing instrument) (by firearms) (cut) (dissection) (incised) (laceration) (penetration) (perforating) (puncture) (with initial hemorrhage, not internal). (Laceration ICD codes are too extensive to list in detail here.) For fracture with open wound, see Fracture.

TABLE 22-	4 CPT/Billing Codes		
Benign Skir		Intermediate S	Skin Repairs
11200	Tags, up to/including 15 lesions	12031	SATAL <2.6 cm
11201	Tags, each additional 10 lesions	12032	SATAL 2.6-7.5 cm
11400	TAL < 0.6 cm	12034	SATAL 7.6–12.5 cm
11401	TAL 0.6–1.0 cm	12035	SATAL 12.6–20.0 cm
11402	TAL 1.1–2.0 cm	12036	SATAL 20.1–30.0 cm
11403	TAL 2.1–3.0 cm	12037	SATAL >30.0 cm
11404	TAL 3.1–4.0 cm	12037	NHFG < 2.6 cm
11406	TAL >4.0 cm	12042	NHFG 2.6–7.5 cm
11420	SNHFG < 0.6 cm	12042	NHFG 7.6–12.5 cm
11421		12045

# LACERATION AND INCISION REPAIR: NEEDLE SELECTION

William Jackson Epperson

A large variety of needle types have been developed for specific surgical needs. The needle facilitates the appropriate placement of suture. Inappropriate needle selection can damage the tissues, causing poor results and delayed healing. For example, a tapered needle with a round shaft is needed in suturing bowel, where prevention of leakage is imperative. A cutting needle would never be appropriate in the reanastomosis of bowels or blood vessels.

Most needles are made of noncorrosive stainless steel. Through a process of heating the metal, maximum strength and ductility (the ability to bend under pressure without breaking) are achieved. Each needle type is sharpened to a varying degree depending on its use. Also, to assist with passage through tissues, most needles receive a thin coat of silicone or other lubricant.

# **NEEDLE DESIGN**

The surgical needle is composed of a *swaged eye* or *shank*, a body, and a *point* (Fig. 23-1). There are *three types of needles*: the closed eye, the French (split or spring) eye, and the swaged eye. Both closed-eye and French-eye needles must be threaded (Fig. 23-2). Since the 1960s, needles have been almost exclusively swaged because threaded needles have many undesirable characteristics. The swaged portion of the needle is now commonly referred to as the *shank*. Within the shank the metal is literally molded around the suture, which alleviates most needle-to-suture attachment problems and prevents the repeated use of a dull, nonlubricated, or contaminated needle, problems associated with threaded needles.

Many terms have been developed by suture manufacturers to categorize their products for different purposes and to denote their size. Unfortunately, there is no standard nomenclature. On thick skin, "for skin" (FS) needles are acceptable, and most have a reverse cutting edge. On cosmetic areas, plastic (P), plastic skin (PS), premium (PRE), or precision cosmetic (PC) needles may offer some minor advantages for the surgeon, but at a significantly greater cost. These initial designations for the needles are the common nomenclature used by Ethicon, Inc. (Somerville, NJ) as marketing terms for their needles. Ethicon, Inc. manufactures over 80% of the needles used in North America. Other manufacturers include USSDG (Norwalk, Conn) and Surgical Specialties Corporation (e.g., LOOK, Sharpoint; Reading, Penn), who use somewhat similar needle description nomenclature.

Generally, a larger needle is used for deeply buried sutures, whereas a smaller needle can be used to close a thin layer of skin. Location of closure is also important. For instance, facial closures are often done with a P-3 needle, whereas other areas with thicker skin require an FS-2 or FS-3 needle. It is important to review the descriptions of the needle on the outside of the suture package, and often a picture of the needle will aid in proper needle selection.

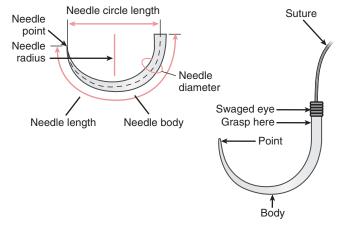

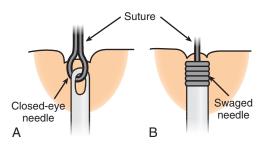

Figure 23-I Anatomy of a surgical needle.

Needles should be handled only with needle holders. A proper-sized, high-quality needle holder is needed for suturing; no other instrument is acceptable for this task. This is one instrument that is worth investing in because it can make the suturing experience satisfying or totally frustrating. In general, gold-handled instruments are of superior quality. The needle should be grasped by the needle holder at a position about one needle holder's width past the curved center of the needle. Only one click of needle holder pressure should be applied to hold the needle in place. If the needle slips it may be that the needle holder is old and no longer will hold the needle, or the suturing attempt being made is not commensurate with the needle size and technique being applied.

**Figure 23-2 A,** Tissue disruption can be caused by the double-suture strand with a closed-eyed needle. **B,** Tissue disruption is minimized by a single-suture strand swaged to needle.

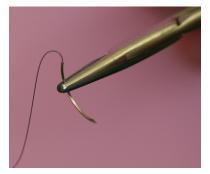

Figure 23-3 Needle holder with needle in place.

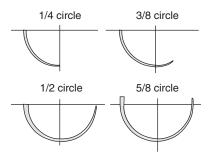

Figure 23-4 Needle body shapes.

A hemostat or other grasping instrument is not an acceptable substitute for a needle holder when suturing. The needle will easily roll out of position because it requires a flat surface to maintain its operative position. All grasping of the needle with any instrument causes a weakening of the metal with risk of breakage. This is less of a concern when a proper-sized needle holder is used with prudent application of force in achieving desired surgical results.

The needle should be grasped below the shank portion, but beyond the mid-body region (Fig. 23-3). The swaged metal must be sufficiently soft to crimp firmly around the suture and lock it in place. Therefore, if the needle is grasped by the needle holder at the shank, it can easily bend and weaken. The body of the needle is firm, not malleable, and less likely to bend. The tip of the needle holder should just cover the needle, and the handle should be closed only to the first or second ratchet. During needle placement the force must be advanced in the direction of the curvature of the needle. The wrist must be everted and supinated as the needle goes through tissue to avoid undue pressure and bending.

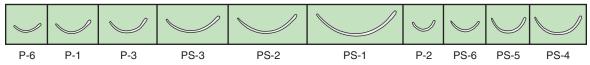

The body of the needle is important for both strength and grasping by the needle holder. Various shapes of the body are important for added strength as well as for matching the flow of the needle through the tissues as directed by the point. A flattened body with concave or convex surfaces helps to reduce unwanted needle rotation when suturing. The shape of the body of the needle allows for a variety of uses (Fig. 23-4). In general, a 3/8-inch curvature is adequate for most cutaneous procedures (Fig. 23-5).

Needle points are the most important needle consideration. The basic types of needle points include *cutting*, *tapered*, and *blunt* (Fig. 23-6). The *blunt-point* needle is used for friable parenchymal tissue such as liver and kidney. This point allows for dissection through tissues, avoiding the trauma of a cutting needle.

The two opposing edges of a *cutting needle* allow for easier passage through tough tissues. This makes cutting needles ideal for suturing skin with its dense supporting structures. However, these cutting edges have their drawbacks when it comes to tendons and oral mucous membranes, which are easily damaged by overcutting.

The conventional cutting needle has a cutting edge on its inside or concave curvature. The inside cutting in the direction of force is a negative characteristic of this needle. The suture force tends to concentrate at the apex of the triangle, and the tissues outside of the desired suture channel are cut. For this reason, a conventional

# **Ethicon** Precision point needles

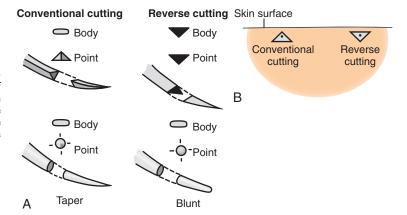

#### Precision cosmetic needles

#### Davis & Geck

Figure 23-5 Ethicon and Davis & Geck (Kendall) needle nomenclature for facial closures (actual sizes).

**Figure 23-6 A,** Needle points and body shapes. **B,** In conventional cutting needles the pressure is concentrated on the apex of the triangle, and the needle thereby has a tendency to tear through tissue. In reverse cutting, the advantage of piercing through tissue still exists, but the pressure from the suture is distributed over the whole base so unwanted tearing is reduced. *Black dot* indicates suture.

cutting needle is rarely used compared with the reverse cutting needle (see Fig. 23-6).

The reverse cutting needle has its cutting edge on the outer curvature of the needle. This provides a flat surface along the inner edge, thereby reducing the incidence of sutures pulling through tissues into the margin of the wound. Unless specified otherwise, a "cutting needle" now refers to a reverse cutting design.

Tapered cut or round needles have an oval body to reduce twisting in the needle holder. These points are useful in less dense tissues that require small holes and minimal tissue injury, such as fascia or bowel.

#### **COMPLICATIONS**

When inappropriately small suture needles are chosen, there is a high risk of needle bending or breaking. A lost needle tip can be a serious, time-consuming intraoperative problem. Other causes of needle breakage include an unexpected encounter with bone or scar tissue, inappropriate angle of penetration, or the use of a reshaped needle that was bent during usage.

The loss of the whole needle in tissues can be avoided by using good judgment in matching tissue bites to needle length. Avoid firm grasping of the suture material near the shank with the needle holder or forceps because it can weaken or cut the suture material, leaving an unattached needle. This free needle becomes a great risk to the surgeon for needlestick injury as well as an opportunity for complications in the patient.

The shank is the thinnest metal portion of the needle, and this thin metal is, of course, the weakest portion of the needle. Care must be taken never to apply force or attempt to use the needle holder on the shank when suturing. When a needle bends during suturing, the act of straightening it further weakens the metal. The surgeon must remain aware of this potential cause for complications.

In addition, multiple needle passes through tissues and associated frequent re-arming of the needle holder wears away the needle lubricant coating, which increases the force required for subsequent needle passes.

#### **CONCLUSION**

Often an ordinary suturing procedure becomes more difficult than expected. This difficulty can be ameliorated by reassessing the appropriateness of the instruments being used. Needle selection is often a key factor in facilitating the ease of the operation and ensuring ultimate good surgical results.

# LACERATION AND INCISION REPAIR: SUTURE SELECTION

William Jackson Epperson

Numerous suture types have been developed for specific tissue properties in the body. The qualities most important for suture include flexibility, strength, secure knotting, and a low propensity to contribute to inflammation or infection. The goal of suturing is to maintain the approximation of tissue securely until healing allows for tissue strength to be maintained alone.

The two main categories of suture are *absorbable* and *nonabsorbable*. All types of suture are foreign to the body; therefore the degree to which the body reacts against the suture is an important consideration in suture choice.

Suture size is indicated by the use of a "0," with the more "0"s designating smaller sutures (e.g., 4-0 is smaller than 3-0). Suture materials are standardized by specific regulations, which ensure tensile strength consistency.

Absorbable suture is a sterile strand of synthetic polymer or mammalian-derived collagen. The rate of absorption and duration of tensile strength are important considerations. For example, the suture may lose effective strength long before it has been absorbed. Various coatings and materials have been developed to prolong the tensile strength retention of absorbable sutures. These coatings also aid in the passage of suture through tissues by decreasing friction.

The natural absorbable suture (mammalian collagen or gut sutures) are derived mainly from the submucosa of sheep intestine, the serosa of cattle intestine, or the flexor tendons of cattle. They are available in plain or chromic (coated with chromic salts to help delay absorption). Tensile strength is determined by the percentage of collagen in the gut suture. Any collagen materials in the gut suture can cause severe tissue reactions, so purity of the protein is very important. Rare true suture allergy can be caused by foreign collagens or chromic salts in "gut" suture.

Common *synthetic absorbable* suture materials include polyglactic acid (Vicryl), polyglycolic acid (Dexon), and polydioxanone (PDS). These materials have the desirable property of extended time of tensile strength (Fig. 24-1).

Nonabsorbable suture is used for skin and for long-term internal placement such as in cardiovascular, orthopedic, and plastic surgery. Many raw materials are used, including silk, cotton, stainless steel, nylon, polyester, and polypropylene (Table 24-1). Table 24-2 reviews the various features of each of these sutures. All suture materials except stainless steel will lose at least some tensile strength if left in the body for long enough periods.

Nonabsorbable sutures are removed from the skin when no longer needed. In vascular and orthopedic applications there is often a need for more permanent materials that retain their tensile strength. Tendon repair requires prolonged healing time, so sutures need long-term tensile strength to give adequate time for self-repair. Vascular grafts must have the support of suture for an indefinite period. The anastomosis of a graft and a blood vessel is never secured by the fibroblast and collagen of the body alone.

Braided suture adds strength and helps to secure the knotting but is more likely to leak fluid, which is called *capillarity*. This quality increases the likelihood of harboring bacteria and subsequent infections. Monofilament is better to use in the presence of infection, but its knots are less dependable. Tissue reaction is important in delicate tissues in which scar and tissue formation may be a problem, which is why gut suture may not be a good choice for use on the face.

Other suture characteristics are also important. *Tensile strength* is the force necessary for a suture to break divided by its cross-sectional area. Tensile strength can be altered by twisting, braiding, increased age, heating, and moisture. Suture coatings reduce friction when passing through tissues. Braided suture has more friction than monofilaments. Coatings used include silicone, Teflon (DuPont; Wilmington, Del), and wax. Polyglactic suture has also been coated with triclosan, which is an antibacterial agent that may reduce the incidence of staphylococcal infections. *Memory* describes the characteristics of a suture material in returning to its original shape after bending. Increased memory is found in nylon and polypropylene, and their knots are more likely to untie spontaneously.

Sutures are foreign to tissues and all induce inflammatory responses. The larger stranded and multistranded sutures, in general, cause more tissue reactions than thin or monofilament sutures. Synthetic sutures of nylon and polypropylene cause less reaction than silk or surgical gut. The dissolution of absorbable sutures is accomplished by the homeostatic immune response. In general, less immunogenic suture materials are small diameter, synthetic, monofilament, and nonabsorbable. A greater immunologic response comes from suture materials that are larger diameter, natural fiber, multifilament, and absorbable.

Knots are an important consideration in terms of whether they remain tied and do not cause a significant reduction in the tensile strength of the suture material. The knot is the weakest part of the completed suture ligature. Proper knotting technique requires application of the square knot or a double loop followed by a square knot tie. Often knots are accomplished as half hitches that are weak and do not remain secure. The more friction the suture has, the less likely it is to incur slippage and loss of knot integrity. Braided suture knots rarely slip, whereas monofilament often comes untied in the absence of proper knotting technique. For proper tying techniques, see Chapter 25, Laceration and Incision Repair: Suture Tying.

# **CHOOSING A SUTURE**

Each surgeon has his or her own choice of suture based on training and individual preferences. Choosing the appropriate suture characteristics in relation to the various applications will facilitate the operation and lead to an acceptable result. Table 24-3 generalizes some recommendations for sutures commonly used in an office

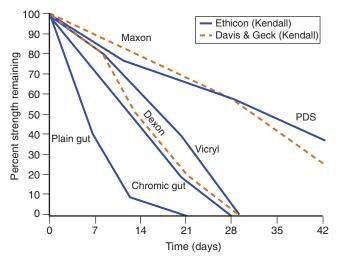

TABLE 24-1 Nonabsorbable Sutures					
Material	Туре	Tensile Strength	Tissue Reaction	Cost	
Silk Nylon (Ethilon, Dermalon)	Braided Mono	Poor Good	High Minimal	Low Low	
Polypropylene (Prolene, Surgipro)	Mono	Excellent	Minimal	High	
Uncoated braided polyester (Dacron, Mersilene)	Braided	Good	Moderate	High	
Coated braded polyester (Ti-cron, Ethibond)	Braided	Good	Moderate	High	
Polybutester (Novafil)	Mono	Good	Minimal	Moderate	

Figure 24-1 In vivo strength retention of absorbable sutures.

Suture	Types	Makeup	Usage	Tissue Reaction	Absorption Time or Rate (total)	Tensile Strength Retention
Absorbable Su	tures					
Gut	Plain multifilament twisted	Mammalian collagen	Superficial vessels and quick-healing subcutaneous tissues	High	70 days	7–10 days
Gut	Chromic multifilament twisted	Mammalian collagen	Versatile; also good in the presence of infection; do not use on skin because of reaction	Moderate	90 days	10-21 days
Polyglycolic acid (Dexon)*	Mono	Synthetic polymer	Buried sutures; good tensile and knot strength	Mild	40% in 7 days	20% in 15 days, 5% in 28 days
Polydioxanone (PDS) <sup>†</sup>	Mono	Polyester polymer	Versatile; body cavity closure; bowel; buried skin suture where more strength and longer retention needed	Mild	210 days	70% in 14 days, 50% in 28 days
Polyglactic acid (Vicryl) <sup>†</sup>	Braided	Coated polymer	Subcutaneous skin; buried sutures	Mild	60–90 days	60% in 14 days, 30% in 21 days
Polyglyconate (Maxon)	Mono	Polyester	Smoother knot and excellent first-throw holding; buried	Mild	180–210 days	80% in 14 days, 60% in 28 days
Nonabsorbable	Sutures					
Cotton	Twisted fibers	Cotton fiber	Ligating, some skin but generally too reactive	Minimal	Nearly permanent, encapsulated in the body	50% in 6 mo, 30% in 2 yr
Silk	Braided	Silkworm-spun fiber	Ligating, some skin but rarely used	Moderate	2 yr	Gone in 1 yr
Steel	Mono	Alloy Fe-Ni-Cr	Tendons, sternum, abdominal wall	Low	Never; encapsulated in the body	Indefinite
Nylon (Ethilon, Dermalon)	Mono	Synthetic polymer	Skin	Very low	20% per year	Loses 20% per year
Polyester (Mersilene)	Braided	Polyester	Cardiovascular, general, and plastic surgery	Minimal	Nearly permanent; encapsulated in the body	Nearly indefinite
Polypropylene (Prolene) <sup>†</sup>	Mono	Synthetic polymer	Skin, vascular, plastic surgery—very "slippery" so needs extra knots; "stronger" than nylon	Minimal	Considered permanent; encapsulated in the body	Nearly indefinite

<sup>\*</sup>Dexon Plus has a synthetic coating to facilitate knot tying and passage through tissue.

TABLE 24-3 Common Sutures for Cutaneous Surgery				
Area of Body	Skin (Interrupted)	Skin (Running Subcuticular)	Buried	
Face Extremities, trunk	5-0 or 6-0 nylon 4-0 or 5-0 nylon	4-0 or 5-0 polypropylene 3-0 or 4-0 polypropylene or 3-0 or 4-0 synthetic absorbable (rarely used on extremities)	4-0, 5-0, or 6-0 synthetic absorbable or 6-0 clear nylon 3-0 or 4-0 synthetic absorbable; occasionally 4-0 polypropylene if quite deep	

setting. In general, the smaller the suture, the lower the tensile strength; thus, more sutures will be needed, but the cosmetic result will be better. Physicians vary greatly in their preferences, and no one suture is satisfactory for all situations. Nylon is a good, all-around, inexpensive material for surface skin suturing. It is not quite as strong or slippery as polypropylene, but it ties easier and takes fewer knots. Polypropylene is stronger and glides through tissue easily, but requires at least three, if not four, knots and still may not remain tight. Polypropylene works well for running subcuticular stitches, and often, because it is stronger, a smaller size can be used for interrupted closures.

# **COMPLICATIONS**

Suture breakage can be a time-wasting inconvenience for the surgeon and present significant problems for wound healing. The direct application of inappropriate force to suture material may result in suture breakage, as may irregular surgical angles, rapid suture decomposition by infection, difficult-to-access surgical sites, and postoperative patient mobility. Complications may be reduced by applying an increased number of ligatures and by using suture diameter that is commensurate to the forces most likely to be experienced in the surgical situation. Of course, almost all applications of suture can reduce tissue blood supply, and proper surgical technique reduces the incidence of this complication. Running loops of suture in an effort to accomplish quicker wound closure increases the risk of wound dehiscence in the event of suture breakage. Interrupted suture ligatures greatly reduce this complication, but are extremely time consuming compared with running ligatures.

The tensile strength of the suture can be reduced by actions that cause fragmentation or splitting of the suture fibers, also known as *frays*. Common causes include friction caused by tying, especially with tension applied during long knot rundowns. Also, scar tissue, bone, or foreign material may damage suture within tissues, whereas retractors, forceps, clamps, and needle holders can cause damage to suture within the surgical field.

# **TIPS**

When purchasing your supply of office sutures, consider the following:

- 1. Nylon is most commonly used and least expensive for interrupted sutures in the skin (3-0 through 6-0).
- For running subcuticular sutures, nylon will work, but only for shorter lengths. It is not very slippery and may break on removal. Polypropylene (Prolene) is "more slippery" and stronger.

- 3. For deep inverted sutures, generally use polyglactic acid (Vicryl) or polyglycolic acid (Dexon). Vicryl lasts a little longer.
  - If longer retention and greater strength are desired, consider polydioxanone (PDS II).
  - If a permanent deep suture is preferred, consider clear nylon.

# LACERATION AND INCISION REPAIR: SUTURE TYING

Ronald D. Reynolds

The knot is the weakest point of any suture. Even when properly tied, the knot is less than half the strength of the suture material that it is tied in and will always be the point at which a suture fails. Knots will slip apart if not correctly constructed. If excessive tension is applied, even to a properly tied suture loop, it will break at the knot because of internal shearing forces.

It is incumbent on the physician to know what suture material and size to use for each type of tissue that is to be approximated (see Chapter 24, Laceration and Incision Repair: Suture Selection). Once a suture is placed, it must be tied in an appropriate manner—not too tight or too loose and with a knot that will not fail before the tissue has healed. The knot must not be excessively large because inflammation and infection are directly correlated with knot volume in tissue.

# **GENERAL PRINCIPLES OF KNOT TYING**

A few generalities can be made about all knot tying. The suture material must always be treated with respect. Grasping the suture with an instrument will weaken it and thus should be avoided, except when holding a tail that will be cut away after an instrument tie. Shearing forces created by sawing two strands upon one another will weaken the strands. The first throw of a knot should just approximate the tissue, but subsequent throws must be tied firmly for knot security. Ideally, knots should be tied with equal tension on both strands. Tension should be applied parallel to the loop being closed and along the axis of the knot being tightened. Excessive throws do not add to knot security; they only add time and bulk.

#### **KNOT MECHANICS**

Suture knots are at the mercy of a number of factors. If the knot is tied in a *monofilament* material such as gut, nylon, polypropylene (Prolene), or polydioxanone (PDS), the *coefficient of friction* within the knot will be low, leading to a tendency to slip. These materials also have *memory*, a tendency to maintain the shape in which they were manufactured, giving a straightening tendency that can lead to untying. The *pliability*, or ability to form a tight loop, of nylon is higher than that of the other monofilament materials. Braided *multifilament* suture materials such as silk, polyester (Mersilene, Ethibond), polyglactin (Vicryl), and polyglycolic acid (Dexon) have a higher coefficient of friction and less memory, making them easier to tie and less prone to slippage. The absorbability of a suture does not have a direct influence on its tying characteristics.

When knots are tied, great care must be taken as to the details. The *square knot* (Fig. 25-1A) is the prototype suture knot because it is easy to tie, is strong, and does not loosen easily. Each twisting layer of the knot is called a *throw*. A square knot is constructed of one helical twist for the first throw, followed by one helical twist in

the opposite direction for the second throw. If both helices are in the same direction, a *granny knot* (Fig. 25-1B) results. Granny knots slip much more easily than square knots and therefore should be avoided when tying sutures.

After a helix for a knot throw is made with two suture strands, it must be kept in a helical configuration as the knot is tightened. If too much tension is applied to one strand, that strand will straighten and a half hitch (Fig. 25-1C) in the other strand will result. As is obvious by its appearance, half hitches will slip on the straightened member of the suture and, therefore, are also to be avoided. It is unfortunately common for a physician who thinks that square knots are being laid down to instead make a series of slipping half hitches (Fig. 25-1D). This is due to too much tension being applied to one strand during the tightening phase of tying.

If there is excess tension on wound edges when a square knot is being tied, the first throw of the knot may loosen before the second throw is placed and allow the edges to gape apart. The *surgeon's knot* (Fig. 25-1E) is an adaptation of the square knot with two helical twists in the first throw. This additional twist increases the friction within the first throw and helps to hold it tight while the second throw is made. It is almost always used, but, whenever a surgeon's knot seems necessary, the clinician should always be sure that the deep space has been closed with a deep suture if possible to approximate wound edges and take tension off the skin closure.

# **CHOOSING A SUTURE TYING TECHNIQUE**

All physicians learn knot tying skills during medical school and become familiar with one-handed and two-handed ties, as well as instrument ties. There are some important points to consider when you decide which of these tying techniques to use.

Most procedures performed by primary care physicians are office procedures done on the skin. Physicians cannot afford to waste excess suture material just for the sake of knot tying. Studies of the economics of suture tying show that at least two to four times as many sutures can be constructed in a given length of suture material with an *instrument tie* than with a *hand tie*. Although instrument tying is slightly slower than hand tying, it is much more economical and is the preferred technique for all skin procedures.

If a hand tie is to be done, the preferred method is the two-handed tie. Although the one-handed tie may be slightly faster than a two-handed tie, it is difficult to do well. One-handed ties are prone to creating a series of half hitches, because it is common to keep too much tension on one strand during tying. Also, because most wounds are sutured with the needle movement directed toward the physician and it is this closest strand (with its needle attached) that is primarily manipulated during a one-handed tie, there is a possibility of needlestick injury during a one-handed tie. Therefore one-handed tying is not covered in this chapter.

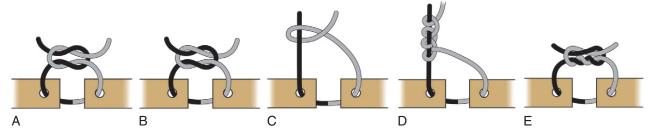

Figure 25-1 Suture knots. A, Square knot. B, Granny knot. C, Half hitch. D, Series of "square" half hitches. E, Surgeon's knot. (Redrawn from Zimmer CA, Thacker JG, Powell DM, et al: Influence of knot configuration and tying technique on the mechanical performance of sutures. J Emerg Med 9:107–113, 1991.)

#### HOW TIGHT TO TIE THE LOOP

To appropriately approximate tissue, sutures must bring wound edges into apposition, but not place excessive force on the tissues ("approximate but don't strangulate"). If a suture loop is tied too loosely, a gap persists and the wound will not heal by primary intention but, instead, must heal by secondary intention from deeper within the defect. If tied too tightly, a suture loop will strangulate the tissue within, creating ischemia and poor wound healing. A too-tight skin suture will cut into the skin surface across the wound, creating a permanent "railroad track" scar.

Whether incised by accidental laceration or by an intentional surgical wound, all tissue will swell somewhat from the inflammation that is attendant in the healing process. Some allowance must be made for this anticipated swelling when tying each suture. It is the tension of the first throw, and maintenance of this tension while the second throw locks it in place that is critical. Additional throws beyond these do not change the tension within the original loop.

As tension is applied to the first throw of a knot, the tissue edges should just barely touch together. If the edges are bunched together initially, subsequent swelling will make the loop too tight. With skin sutures, two subtle indications of excess loop tension include (1) a puckering effect of each suture that makes the wound mound up slightly between each loop, and (2) a pale color of the skin underneath the suture. It is far better to remove and replace an improperly tied suture than to leave it and hope for the best.

# **How Many Throws to Place**

How many additional throws to place on top of the basic square or surgeon's knot for knot security is a slippery question. Suture manufacturers will only say "additional throws as indicated by the surgical circumstance and the experience of the surgeon." (Believe me, they won't give a real answer, even when pressed. I've tried. Medicolegal concerns keep them from committing themselves.)

For a knot to be secure, additional throws are needed beyond the basic two throws. Without added throws, the knot will slip loose when tension is applied to the loop. Any loosely tied knot will slip, so all throws past the first must be tied quite firmly, but without excessive force that will damage the integrity of the suture material.

Placing more throws than needed will unnecessarily add operative time and increase the bulk of the knot, without adding strength to the knot. Extra throws in a skin suture knot add operative time but have no consequence for the tissue because they are not buried. If the knot is buried, as in a subcuticular suture, additional bulk adds to the tissue reaction and can increase the infection risk. It is therefore necessary to know the minimum number of throws to tie a secure knot in a variety of suture materials.

As a general rule, studies have shown that when 3- to 4-mm tails are left, monofilament materials need a total of four firm square throws to be secure, and braided materials need three. Obviously, if the knot is not tied squarely (made of alternating throws with helices in different directions), is tied loosely, or consists of half

hitches rather than square throws, even the recommended number of throws will not suffice.

There are two exceptions to this general rule. First, nylon is pliable enough that it holds with three firm square throws. Second, when the suture is cut on the knot and no tails are left, one additional throw is required for knot security.

#### **TECHNIOUES**

#### Instrument Tie

An instrument tie uses the needle holder to form the twists in each throw. Directions are for a right-handed physician. Left-handed physicians can reverse the handedness in the directions and look at the figure in a mirror.

- 1. Place the suture moving toward yourself, and pull it through until just 2 to 3 cm of the tail is left outside the entry hole. Drop the needle beside the wound to minimize needlestick risk. Pick up the long end of the suture with your left thumb and index finger about 8 cm from its exit, and hold it above the wound.
- 2. Create the first throw by making a single twist (for a square knot) or double twist (for a surgeon's knot) around the tip of the needle holder with the long strand. To do this, the needle holder is held closed, but not locked, facing toward the left. The instrument tip approaches the long strand moving toward the physician. Both it and the long strand are moved in a clockwise motion to wrap the strand around the tip (Fig. 25-2A), with care taken not to pull the suture through the wound. Grasp the short end with the very tip of the needle holder. Pull the short end through the loops around the needle holder's tip (Fig. 25-2B). Keep even tension on both strands as you pull the short strand toward you with the needle holder and the long strand away from you with your left hand (Fig. 25-2C). The sutures should maintain a helical configuration all the way down to the wound. Apply enough tension to just appose the wound. Release the short end.
- 3. The second throw is created by reversing the rotation of the long strand around the needle holder tip. While still holding the long strand in the left hand, bring it toward you while moving the needle holder away from yourself. As the needle holder tip touches the long strand, wrap counterclockwise around it (Fig. 25-2D). Again grasp the short end in the needle holder tips (Fig. 25-2E), and pull the short strand away from yourself while pulling the long strand toward you (Fig. 25-2F). Carefully pull the throw down square to lock the knot. As you tighten this critical second throw, don't pull hard enough to disturb the first throw—this might loosen the careful apposition.
- 4. Additional throws must be made, with the number depending on the suture material and circumstances. Repeat the cycle of clockwise–counterclockwise throws, being careful to lay each throw down with opposite rotation to the last throw. Tie each throw square (not half-hitched) with firm and even tension on both ends as the knot is snugged tight. When the knot is

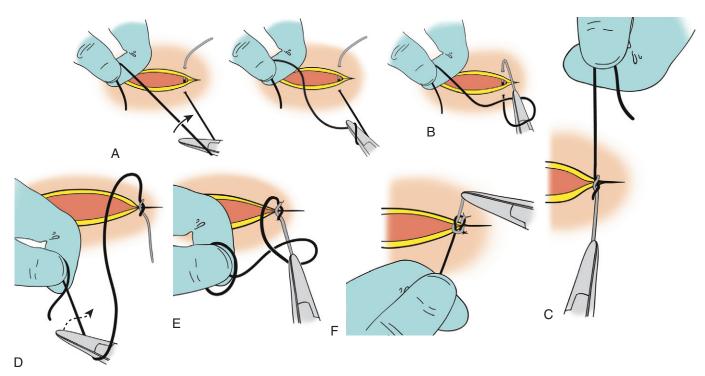

Figure 25-2 Instrument tie. A, The first clockwise wrap around the needle holder tip. B, Grasping the tail. C, Tensioning the first throw. D, Counterclockwise wrap for the second throw. E, Grasping the tail. F, Tensioning the second throw.

completed, excess material is cut away, either on the knot if it is to be buried or leaving 3- to 4-mm tails if it is a skin suture.

#### Two-Handed Tie

This version of the two-handed tie presumes that the suture to be tied has been sewn toward you, with the needle on your side of the wound. Following this sequence prevents you from having to cross your hands over the top of the wound, a motion that blocks your vision of the knot being formed.

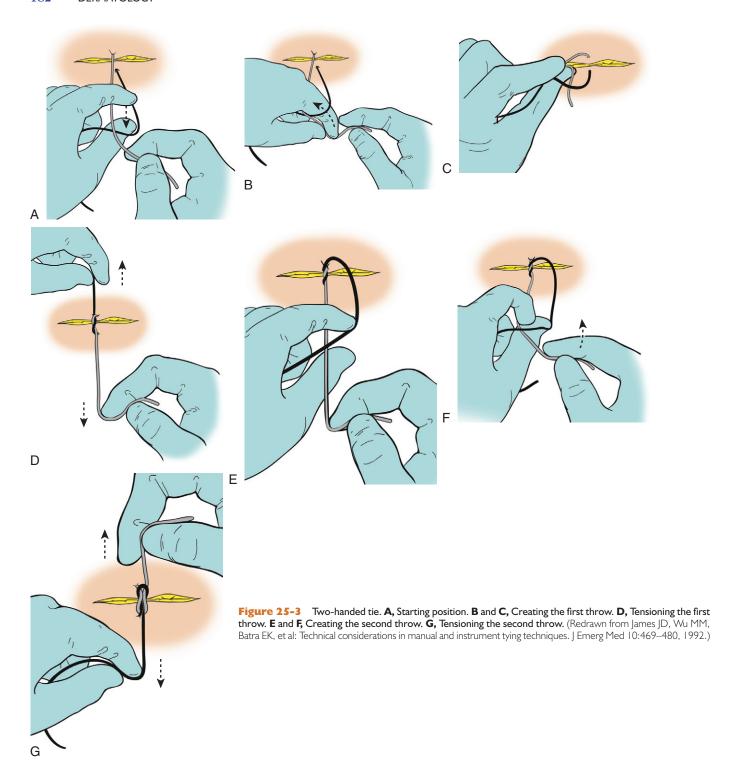

- 1. The two-handed tie starts like the instrument tie with the suture being placed in the tissue and being pulled through, but leaving about 10 cm of the tail outside the wound. Grasp the tail in your right hand and the long end in your left hand. Palms are up when initially grasping the strands, which are held between the last three fingers and the palm. To start the knot, grasp the short end between your right index finger and thumb. Use the back of your left thumb to hold the long end as shown. Lay the short end across the side of your left thumb to form a loop (Fig. 25-3A).
- 2. Drop your left index finger to contact the pad of your left thumb and hold the loop open. Maintaining the pinch, drop the loop off your thumb and move down to pinch the short end (Fig. 25-3B), leaving your left index finger inside the loop. Push the free end up through the loop with the left thumb by extending your left wrist (Fig. 25-3C). Release the free end from your right hand and regrasp it as it is pulled through the loop. This same maneuver can be redone to make the second twist needed for a surgeon's knot. Draw down the first throw and tighten evenly by bringing your left hand away from and your right hand toward yourself (Fig. 25-3D).
- 3. The second square throw is created by reversing these maneuvers. As you draw the long end back toward yourself with your left hand, use your left index finger to begin to create a loop. Reach

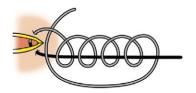

- under the short end with your left thumb (Fig. 25-3E), and push your thumb up to hold the side of the loop. Bring your left thumb and index finger together inside the loop (Fig. 25-3F). Lift the short end in your right hand, and place it in the pinch of your left thumb and index finger. Push the short end down through the loop with your left index finger, release it from the right hand, and then regrasp. The second throw is then brought down by bringing the right hand away and the left hand toward you (Fig. 25-3G). Be careful not to disturb the first throw as this critical second throw is tightened.
- 4. Additional throws are added as needed by alternating the same process of the first and second throws. Alternating the helix of the throws will keep the knot square. When the knot is completed, excess material is cut away, either on the knot if it is to be buried or leaving 3- to 4-mm tails if it is a skin suture.

# **Half Blood Knot**

It is useful to know one additional knot for tying suture—the half blood knot. Fishermen use this slipping knot to tie lures onto the end of fishing line. It is a very strong knot, retaining almost all of the strength of the suture material. The half blood knot is the best knot for securing the beginning of a running suture, particularly with monofilament material. General surgeons commonly use it to secure the beginning of a running suture in the linea alba when closing the abdomen, but it also works well to start a running cuticular or subcuticular suture.

After the suture is placed in the tissue, the tail is passed around the working strand of the suture. Four twists of the tail around itself are made. More than four twists do not add to the strength of the knot. The tail is then passed up through the first loop, parallel to the working strand (Fig. 25-4). The knot is tightened by pulling on the tail with a needle holder, then is slipped down to secure the tissue. The working end continues on to construct a running suture line.

**Figure 25-4** Half blood knot. The tail is passed around the long strand, then loops four times around itself, then the tail is put through the first loop.

#### **COMMON ERRORS**

- If the first throw of a knot slips loose before the second throw can be tied, additional measures are needed:
  - A double helix can be used as the first throw, creating the surgeon's knot.
  - An absorbable deeper suture can be placed to take tension off of the closure.
  - The extra hands of an assistant can hold the wound edges together as the suture loop is being tied.
  - A helper stitch can be placed and later removed. A horizontal mattress suture is placed in the middle of the wound to bring the skin edges partway together. Once the wound is completely closed, this "helper" stitch is often loose and can then be removed.
- A series of half hitches is tied rather than locking square knots. To prevent this, the surgeon must apply even tension to both strands as the knot is tightened, rather than hold one strand taut and tighten the other.
- The knot is tied too loosely. This may be caused by two different problems. First, the first throw must be tied tightly enough to just appose the wound edge. Second, the surgeon should not pull tension on either strand as the second throw is tied because this often loosens the first throw.
- The knot is tied too tightly. As each knot throw is constructed, attention must be given to not strangulating the tissue because this can lead to tissue ischemia and necrosis. The common result of too tight a suture loop is a "railroad track" appearance of the scar when the sutures are removed. It is best to remove and replace an improperly tied suture.

#### **CONCLUSION**

Suture tying is an art that develops with experience. Close attention to detail is necessary when approximating tissue. The goal is to bring tissue edges into apposition without causing strangulation inside the loop as postoperative swelling develops. The instrument tie is preferred for skin sutures. If a hand tie is to be done, the two-handed technique is preferred. The physician must tie firm, square throws by using even tension on each end and must know how many throws to place with each type of suture material to ensure knot security.

# MUCOCELE REMOVAL

Andy S. Barnett

Oral mucous cysts (mucoceles) form as a result of obstruction or trauma involving the ducts of minor salivary glands. Mucoceles are the most common benign soft tissue mass of the oral cavity. Mucoceles occur most frequently in the mucosa of the lower lip. They appear as soft, nontender, compressible lesions with a pink or bluish tinge. Typical size ranges from a few millimeters up to 1 cm, but can be much larger. Superficial mucoceles may rupture and not recur, but larger lesions usually remain persistent or recurrent unless treated adequately.

#### **ANATOMY**

Because most labial mucoceles occur as a result of mild trauma, location adjacent to the lower lip incisors is most common. Lesions on the lower lip can occur in any layer of tissue from the upper mucosa to beneath the submucosa and usually involve minor salivary glands without the involvement of significant neurovascular structures.

# **INDICATIONS**

- Growth, pain
- Lesions refractory to superficial treatment (e.g., simple puncture or topical cryotherapy)
- Uncertain of clinical nature and biopsy is indicated
- Cosmetic concerns

#### **CONTRAINDICATIONS**

- Atypical location (e.g., gingival or sublingual)
- Atypical gross appearance when perhaps just a biopsy is indicated
- Pulsating mass (consider an arterial aneurysm) (relative)

# **EQUIPMENT**

- Lidocaine 2% with 1:100,000 epinephrine
- 1- to 3-mL syringe with a ½- to 1-inch, 27- or 30-gauge needle
- Scalpel with no. 11 blade and possibly a no. 15 blade
- Cryocautery or electrocautery unit

# **PRECAUTIONS**

Depending on location, consider a proximal duct stone or tumor occluding the duct. Be sure to include any unusual or palpable/ thickened tissue in the specimen. Lesions that are atypical in appearance or location should be sent for pathologic evaluation to exclude carcinoma.

#### PREPROCEDURE PATIENT PREPARATION

See the sample patient education handout titled "Mucocele Treatment" online at www.expertconsult.com.

#### **PROCEDURE**

#### **Small Lesions or Initial Treatment**

An injection of lidocaine with epinephrine is given *under* the mucocele to produce anesthesia and to minimize bleeding by inducing vasoconstriction. The injection will often elevate the lesion, making it easier to see. Injecting in or above the lesion may have just the opposite effect.

With a no. 11 blade, a small stab wound is made in the cyst laterally, and the seromucinous contents are expressed. A freeze of the lesion (see Chapter 14, Cryosurgery) is performed to produce a 2- to 3-mm rim of ice around the lesion. As an alternative to cryotherapy, electrocautery may be used to lightly desiccate the lesion after incision and drainage. The ball cautery tip can be inserted directly into the cavity.

# **Larger Lesions**

Because the tissue is so pliable it is often difficult to stabilize the lip. Consider using a large chalazion clamp, which also effectively controls bleeding.

# Option I

For larger lesions, recurrence is less likely if the roof is shaved off with a no. 15 blade before proceeding to cryotherapy or electrodesiccation (Fig. 26-1). Compress the area firmly between the fingers to reduce bleeding. If cryotherapy is chosen, hemostasis should be obtained before the freeze. A chemical coagulant, such as Monsel's solution, is useful here. The wound is allowed to heal by secondary intent, which takes 5 to 7 days. Caution the patient not to "bite" on the areas, which is tempting to do.

#### Option 2

Alternatively, after anesthesia, use a radiofrequency loop (cutting 20 W and coagulate 30 W or, if a single "cut and coag" setting available, about level 3 or 4) to remove the top of the lesion. Be careful not to go too deeply. Mucinous material appearing much like saliva will often come out of the cyst. A deeper wall of the cyst is usually evident at this point. Generally, a ball electrode is used to destroy the base, or cryotherapy can be considered.

# **Recurrent Lesions**

Recurrent lesions may be retreated as described previously, but with a more aggressive approach. Persistently recurrent lesions or cysts located more deeply in the submucosa may need to be completely excised or marsupialized with interrupted fine absorbable sutures around the margins of the lesion (Fig. 26-2).

A micromarsupialization technique (Fig. 26-3) has recently been described that involves the placement of a 4-0 silk suture through the widest diameter of the dome of the lesion without involvement of the base. A surgical knot is made and the suture is left in place

Figure 26-1 Mucocele removal. A, Large mucocele on the lip that recurred after previous incision, drainage, and cryosurgery. B, The lip is stabilized for administration of local anesthesia with lidocaine and epinephrine. C, The protruding tip of the mucocele is shaved off with a no. 15 blade. D, Preliminary hemostasis is achieved with Monsel's solution. E, Liquid nitrogen is sprayed to destroy the underlying lesion. F, Cryospray is continued until a 2-mm halo of normal tissue is frozen around the affected area. G, Electrosurgery is used to achieve final hemostasis after cryosurgery. (From Usatine RP, Moy RL, Tobinick EL, Siegel DM [eds]: Skin Surgery: A Practical Guide. St. Louis, Mosby, 1998.)

for 7 days. Patients must return to have the suture replaced if it is lost during this 7-day period.

#### SAMPLE OPERATIVE REPORT

Procedure: Mucocele excision (or destruction)

Indication: Lower lip mucocele, refractory to simple cryotherapy Consent: A consent form was signed and witnessed after a discussion with the patient/guardian of the *risks* (including but not limited to pain, bleeding, infection, scar formation, slow healing, recurrence of lesion, and failure to diagnose more serious pathology), *benefits* (treatment of lesion), and *alternatives* (including but not limited to simple aspiration, topical cryotherapy, and watchful waiting).

**Technique:** The mucosa surrounding the lesion was cleansed with Betadine and then anesthetized with lidocaine 1% with epinephrine 1:100,000 through a 30-gauge needle, using a total volume of 3 mL. Anesthesia was confirmed and then the lesion was unroofed around the margins of the dome with a sterile no. 15 blade. The removed portion was sent to pathology for histologic evaluation. Hemostasis was achieved with application of Monsel's solution. The base of the lesion was frozen with a 2-mm rim of normal tissue included for 5 seconds. Final hemostasis was

achieved with brief application of electrocautery to any visible areas of bleeding. Antibiotic ointment was applied to the lesion.

Complications: None

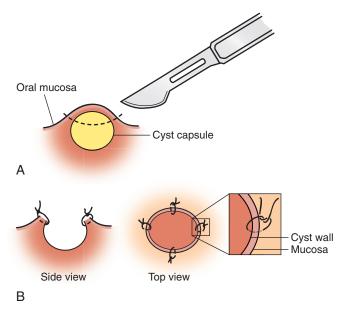

Estimated blood loss: Less than 5 mL

Follow-up: If needed for any signs or symptoms of infection or recurrence of lesion and pending the pathology report.

#### **COMPLICATIONS**

Postoperative complications are very rare because of the forgiving nature of oral mucosal tissue.

- A minimal amount of postoperative bleeding can be controlled with direct pressure and should resolve within hours.
- Any infection should be treated with antibiotics to cover typical oral pathogens.
- Pain can be treated with over-the-counter (OTC) medications.
- If the biopsy specimen indicates atypical, dysplastic, or neoplastic tissue, conservative reexcision or referral should be considered based on the findings.
- Recurrence is the most common complication and can be dealt with using a more aggressive approach, as noted previously, or with referral.

**Figure 26-2** Marsupialization technique to allow continued drainage and promote epithelialization of mucocele cyst. **A,** Unroof the cyst with a no. 15 blade. **B,** Simple interrupted sutures (4-0 or 5-0 absorbable such as plain or chromic catgut, which dissolves quickly) are placed circumferentially through the cyst and oral mucosa.

 Perforation/"button hole" is a rare complication if the excision (especially with a radiofrequency loop) goes too deep. Often the wound can be left to heal on its own. If it is gaping open, a subcuticular closure may be necessary to limit scarring. Alternatively, an absorbable suture on the mucosal side may close the exterior wound nicely.

# POSTPROCEDURE MANAGEMENT

Frequent topical application of antibiotic ointment may speed healing and prevent irritation of the healing mucosa by the adjacent teeth. Healing, even in delayed cases, should be complete within 2 weeks. Incomplete mucosal healing is suspect for more serious

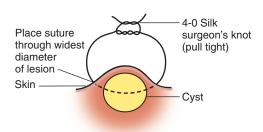

Figure 26-3 Micromarsupialization technique. Remove after 7 days.

underlying pathologic process that requires excisional biopsy. Swelling is to be expected. Pain can generally be controlled with OTC medications.

# NAIL BED REPAIR

John Eckhold

The fingernail is a highly evolved structure designed to enhance the functions of the distal finger. The fingernail functions to (1) protect the distal phalanx, (2) enhance fine touch and fine digital movements, (3) facilitate scratching and grooming, and (4) provide aesthetic and cosmetic considerations.

Any disruption of the normal anatomy distal to the tendinous insertions of the extensor and deep flexor tendons on the finger or the thumb may adversely influence the growth, configuration, quality, and function of the nail plate unit. Sometimes a crushing injury with no penetration of the nail may cause more disfigurement than a sharp penetration, which may extend through the nail to the underlying phalanx. A good primary repair of the injured nail bed yields a high percentage of good results. Meanwhile, the results of excessively delayed repairs and revisions of faulty repairs have a much poorer prognosis. A severely deformed fingernail can be a source of embarrassment or functional impairment.

Consideration for repair includes (1) a thorough anatomic knowledge of the structure to be restored; (2) availability of all the sterile equipment required (including excellent lighting and magnification); (3) the ability to counsel the patient on what to expect over the 6 to 12 months of follow-up that will be required to see the final nail growth; and (4) the ability to recognize those injuries that may exceed the physician's training and experience, requiring referral to a hand surgeon.

Informing the patient *before* any repair effort that the resultant fingernail may be deformed or absent in spite of your best efforts spares the physician and the patient much grief in the end. Preoperative (close-up) photographs provide documentation of the severity of the injury. Patients sometimes forget what the physician had to start with and instead recall only how wonderful the fingernail looked before the injury, expecting the physician to replicate the preinjury status.

#### **ANATOMY**

The nail unit is composed of four distinct epithelial structures: the proximal nail fold, the germinal matrix, the sterile matrix, and the hyponychium (Fig. 27-1). The lateral nail folds (Fig. 27-2) are adjacent normal epidermal folds that border the nail unit laterally. The proximal nail fits into a grove of tissue termed the proximal nail fold. The skin over the dorsum of the nail fold is the nail wall. The eponychium is the thin membrane extending from the nail wall onto the dorsum of the nail. The lunula is the curved, white opacity in the nail, just distal to the eponychium. It is the indicator of the junction between the germinal and sterile matrix. The germinal matrix is the most important component of the nail unit because it is responsible for the formation of the nail plate. A detailed anatomic understanding of the perionychial components of the nail area is required for consideration of nail repairs. The components are as follows:

- 1. Nail plate (nail). Formation begins in the germinal matrix under the proximal nail fold. It is made up of desiccated, keratinized, squamous cells. Note how the nail plate fits into the groove of the proximal nail fold (see Fig. 27-1).
- 2. Nail bed. This lies under the nail plate, beginning at the proximal edge of the nail matrix and continuing until the hyponychium. It is very vascular and thus appears pink. The space between the nail bed and underlying bony structure is very thin (1 to 3 mm) without any subcutaneous tissue. The nail bed consists of the following:
  - The eponychium, which is the dorsal roof of the proximal fold and serves as protection for the underlying germinal matrix and provides a thin layer of cells producing the shiny dorsal nail surface
  - The germinal matrix, where nail production begins and which extends distally just beyond the eponychium to end at the distal border of the lunula
  - The sterile matrix, described by some observers as the "road bed" for the advancing nail, and which adds squamous cells to thicken the nail and enhance its adherence to the nail bed

**NOTE:** The sterile matrix is the distal portion of the nail bed, beyond the germinal matrix. The germinal matrix serves as the nail origin; the sterile matrix only adds to the nail thickness.

- Hyponychium. The distal site where the nail separates from the nail matrix. This area allows the nail to become independent of the nail matrix.
- 4. *Paronychium*. Consists of the lateral nail folds and adjacent cutaneous portions of the lateral nail borders.
- 5. Lateral nail folds. Epithelium bordering the nail laterally.
- 6. Cuticle. The translucent vein of tissue that extends out to the surface of the nail where it emerges from beneath the proximal nail fold. It acts as a barrier or seal to protect the nail unit from external irritants and seals the proximal nail fold to the nail.

# **PHYSIOLOGY**

Nail formation occurs in three layers. The *dorsal* layer arises from the dorsal roof of the nail fold, the *intermediate* layer from the ventral floor and the lateral walls of the proximal nail, and the *ventral* layer from the sterile matrix of the nail bed. The ventral layer provides adherence and enhances the nail thickness to compensate for wearing away on the dorsal surface. The nail grows distally as a result of the force of the pressure placed on the growing cell mass beneath the proximal nail fold. The resultant nail advances distally, hugging the underlying nail bed. Any distortion of these anatomic templates (e.g., proximal nail fold, nail matrix contour and composition) can lead to a deformed and unattractive nail.

Full-length fingernail growth takes 4 to 6 months and is frequently suspended completely for 3 weeks after an acute traumatic event. Fingernails reportedly grow four times as rapidly as toenails. Peak nail growth rate occurs at about 30 years of age.

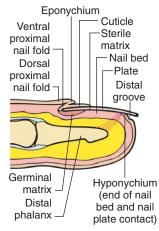

Figure 27-I Sagittal view of the nail and distal phalanx.

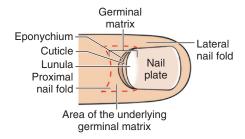

#### **FRACTURES**

An x-ray examination must be performed on any crush, impact, or penetrating injury for possible involvement of the distal phalanx to avoid missing a fracture that may deform the nail bed if left unreduced or unstable. Fractures when accompanied by bleeding from under or around the nail plate, including a drained subungual hematoma, automatically become open fractures and must be treated with the appropriate caution and care. Fractures may require reduction and internal fixation before nail bed repair. Proximal nail bed injuries or avulsions in children are often open Salter epiphyseal fractures of the distal phalanx and should be treated appropriately.

# **SUBUNGUAL HEMATOMA**

See Chapter 35, Subungual Hematoma Evacuation.

The nail bed is a highly vascular area subject to bleeding with either sharp or nonpenetrating blunt trauma. To release the painful smaller hematoma, first cleanse the finger with povidone–iodine solution for several minutes (no anesthesia is required if the nail plate does not need to be removed). Use of a heated (red-hot) paper clip, drill, or microcautery releases the underlying pressure with minimal discomfort. The heated tip passes through the nail with minimal pressure and is cooled by the hematoma, thus not causing injury to the nail bed. The hole should be at least 2 mm in diameter to allow drainage to continue and not seal up when clot forms. If the nail is to be removed to inspect and possibly repair the nail bed, do not place the hole in the nail until the location of the repair site is known. After nail bed repair the vent hole should *not* overlay the repair site directly in order to achieve maximal contouring effect from the replaced nail plate.

**Figure 27-2** Dorsal view of the nail. The sterile matrix underlies the nail plate distal to the lunula (proximal to the lunula is the germinal matrix) under the nail plate.

If the trauma produces a large hematoma suspected of causing a significant nail bed injury, the nail should be removed to facilitate meticulous magnified inspection and careful repair of the nail bed. The prerequisites for inspection include (1) good anesthesia, (2) good light and magnification, (3) essential sterile equipment, (4) sterile saline for irrigation, and (5) adequate retraction assistance to carefully investigate the area deep to the proximal and lateral nail folds.

# **EQUIPMENT**

- Surgical loupes or appropriate magnification providing 2.5× magnification or greater
- Freer septum elevator
- Kutz periosteal elevator
- Small periosteal Key elevator
- English nail splitter
- Small bone rongeur
- Small bone reduction forceps or clamps
- Single- and double-pronged skin hooks
- No. 11 or 15 surgical blade and handles
- Small cuticle scissors
- Needle holders
- Suture scissors
- <sup>3</sup>/<sub>8</sub>-inch Penrose drain
- Small hemostats (2)
- 6-0 and 7-0 absorbable suture (gut or white Vicryl)
- Silicone sheeting (0.020-in thick)
- Petrolatum gauze
- Antibiotic ointment (e.g., Neosporin)
- Small syringe and 30-gauge needle
- Lidocaine 1% to 2% plain (generally no epinephrine in the fingers; however, see the discussions in Chapter 4, Local Anesthesia, and Chapter 5, Local and Topical Anesthetic Complications)
- Adson pickups, with and without teeth
- Finger dressing material, small metal splints, and arm sling for postoperative elevation

# **NAIL PLATE AVULSION (SURGICAL)**

The nail must be removed when there is a large subungual hematoma or when the nail bed injury/laceration is directly visualized or strongly suspected (e.g., there is avulsion of the distal nail from the hyponychium or proximally from the eponychium; see the editor's note after the Bibliography). Verify at this time if there is (1) displaced, unstable phalangeal fracture (requiring fixation); (2) large nail bed avulsion (with missing tissue requiring nail bed grafts); or (3) significant distal amputation of tissue (requiring some type of graft for closure). Consider early referral of the injury if it exceeds personal training, experience, and comfort level.

Exploration of the nail bed can be completed under general anesthesia, scalene block, axillary block, Bier block, or digital block (see Chapter 1, Bier Block, and Chapter 8, Peripheral Nerve Blocks and Field Blocks). The first four can be used with an arm tourniquet and additional sedation as required for longer procedures in which multiple digits are involved. Uncooperative adults and restless children may be managed better with the use of a more formal type of anesthetic setting. Practitioners prefer to save the patients any additional anesthetic charges if possible, but their desire to economize should not compromise the examination or repair in any way when the patient is being uncooperative and moving about during a delicate repair under magnification.

After anesthesia the surgical field is prepared and draped in the usual manner to ensure sterility of the surgical field. At this time, if no other form of tourniquet is in use, a digital tourniquet can be established by use of a sterile ½-inch Penrose drain placed smoothly around the finger and secured with a small hemostat to occlude flow

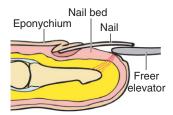

Figure 27-3 Freer elevator placed under the nail. The nail bed is made up of the germinal matrix proximal to the lunula and the sterile matrix distally.

through the digital vessels. Depending on the site of the injury and personal preferences, there are two techniques to remove the nail and visualize the nail bed.

# **Distal Technique**

The Freer elevator is placed under the free edge of the nail (Fig. 27-3) and advanced proximally, following the plane of cleavage between the nail plate and the nail bed. Substantial resistance is encountered along the nail bed until the germinal matrix is reached, where the progress becomes easier. Be careful to avoid advancing the elevator excessively into the proximal nail groove. Now gently work the elevator medially and laterally to free up the last of the soft tissue attachments deep to the nail plate. Place the elevator under the cuticle (on the dorsum of the nail; Fig. 27-4) and dissect under the ventral portion of the proximal nail fold. Continue the dissection laterally on both sides to release any remaining soft tissue attachment while a hemostat is used to apply gentle distal traction, pulling distally. (The goal is to free the nail from any residual soft tissue attachments while not digging too deeply into either the proximal or lateral folds and not worsening any existing trauma.)

# **Proximal Technique**

The proximal approach is often used when a distal cleavage plane cannot be identified because trauma or other pathology (such as onychomycosis) exists. The Freer elevator is placed under the cuticle and advanced to the proximal nail fold and worked to free the proximal and lateral gutters while avoiding damage to the cells in the depth of the folds. Proximal relaxing incisions (Fig. 27-5) facilitate exposure. Advance the elevator to locate the proximal edge of the nail plate. The skin hooks are now used to hold the eponychium folded proximally while the elevator comes over the top, then directed distally just deep to the nail plate as it dissects the plane between the nail plate and the nail bed. Keep the plane of the elevator turned so that the blade conforms as well as possible to the exact curvature of the nail plate in all areas.

# **GENERAL CONSIDERATIONS FOR REPAIR**

When the nail is removed (by the trauma or the surgeon), carefully cleanse the area and examine it with magnification. Make an

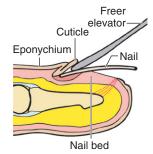

Figure 27-4 Freer elevator placed under the cuticle.

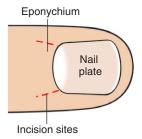

Figure 27-5 Proximal relaxing incisions are used to facilitate exposure.

adequate record of the status of the entire nail bed, the proximal and lateral nail folds, and the hyponychium. Record these findings as part of the operative findings of the distal phalanx.

Carefully scrape any residual nail bed tissue off the nail undersurface, and place the nail in sterile saline to soak while the nail bed is examined. With the tourniquet inflated, cleanse and lavage the nail bed. With excellent light and magnification, the defects can be identified and any gross irregularities trimmed while leaving all the tissue that can be repaired and contoured.

The best sutures for nail bed repair are absorbable 6-0 or 7-0 chromic or Vicryl. (Zook and colleagues [1980] have recommended 7-0 chromic on a micropoint spatula, double-armed, GS-9, ophthalmic needle [Ethicon, Somerville, NJ].) Either a 5-0 or 6-0 monofilament suture is used to repair lacerations or incisions in the skin.

Sometimes the germinal matrix and nail bed may be avulsed from their proximal origin below the proximal fold. When this occurs, use of a monofilament (5-0 or 6-0) horizontal mattress suture (Fig. 27-6) restores the anatomy.

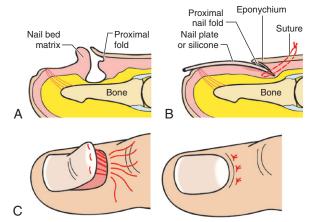

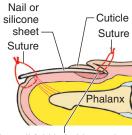

Figure 27-6 Proximal nail bed avulsion. The nail plate has been removed. The nail bed consists of the germinal and the sterile matrix. The matrix extends from a point just distal to the insertion of the extensor tendon to the end of the fingernail attachment. The germinal matrix, which produces most of the nail, begins just 3 to 5 mm proximal and deep to the eponychium and extends distally to the lunula. The lunula is the white portion of the germinal matrix just beyond the cuticle. It marks the end of that portion of the germinal matrix that produces the fingernail. The sterile matrix begins proximally at the distal edge of the lunula and extends distally to the hyponychium. It also plays some role in production of the nail. The eponychium is the flap or tuft of skin that covers over the proximal nail. A, Nail bed has been avulsed from its normal location and displaced dorsally. B, Horizontal mattress suture through the nail wall is used to anchor the nail bed into proper site for healing. Proximal nail fold must be held open (with fingernail or substitute) to prevent scarring down and closure of nail fold. The nail plate or silicone sheet has been placed and anchored (with suture) to hold the proximal nail fold open. C, Appearance of wound after suturing. Sutures are removed from the nail in 3 weeks. The replaced nail or silicone sheet will dislodge in 1 to 3 months. (C, From Chudnofsky CR, Sebastian S: Special wounds: Nail bed, plantar puncture, and cartilage. Emerg Med Clin North Am 10:808-822, 1992.)

The nail fold is held open by the nail or silicone sheet anchored by the horizontal mattress suture

**Figure 27-7** Replacement of the nail or substitute. The nail fold is held open to prevent it from scarring down when the nail bed has been avulsed or severely damaged. The nail itself or a silicone sheet is anchored by the horizontal mattress suture.

After repair of the nail bed, replace the nail. The nail serves as a stent to keep the nail folds open and to approximate the edges of the repair. The nail is well stabilized by the placement of a 5-0 or 6-0 monofilament suture through the nail into the fingertip area.

If the nail is not available or is damaged too badly to use as a stent, alternative materials may be used to provide contouring and protection to the nail bed. Materials such as medical-grade silicone sheeting (0.020 inch), petrolatum gauze, or Xeroform can be shaped to approximate the original nail (Fig. 27-7). They must be placed carefully so that they occupy the space of the proximal and lateral nail folds to prevent them from permanently scarring down. These stents must be anchored by a 6-0 monofilament or similar suture through the proximal portion of the nail folds to ensure their position. These stents will (1) protect the nail bed while healing, (2) maintain the contour of the nail bed and subsequent nail plate, and (3) prevent adherence of the proximal nail fold to the matrix.

Avoid making the postoperative dressing too tight. Instruct the patient to elevate the hand at all times. If nonadherent gauze is used as a stent on the nail bed to hold open the nail folds, the sutures may be removed at 7 to 10 days and gauze will subsequently peel off on its own. If the nail plate has been replaced, it will usually come off in about 3 weeks. Explain to the patient that the fingernail will require 6 to 12 months to grow out and to allow its final status

to be determined. Trim the advancing rough edges to prevent accidental snags.

# **CLASSIFICATION OF NAIL BED INJURIES**

The *type I* nail bed injury (Fig. 27-8A) is a small hematoma (<30% of visible nail) with no major matrix injury. Any injury that produces a subungual hematoma can be classified as a type I injury, including superficial lacerations of the nail bed.

The *type II* injury (Fig. 27-8B) is a large hematoma (>30% of visible nail) with a likely matrix injury (e.g., a severe crushing injury). These injuries have a poor prognosis because the fragments are much more difficult to reassemble anatomically and the viability of this tissue is severely reduced compared with that of simple or stellate lacerations. The need for radiographs to visualize fracture patterns and stability is increasingly important in these more complex injuries. The same general techniques as described previously are used, but more time is spent informing the patient of the poor prognosis and of the likely need for further surgery and possible partial or complete loss of the nail.

A type III nail bed injury (Fig. 27-8C) with or without a hematoma has a phalangeal fracture (distal phalangeal fracture–nail bed lacerations). These fractures may be nondisplaced or displaced and, more important, stable or unstable.

A *type IV* nail bed injury has extensive matrix fragmentation, but the bone is intact. The proximal nail plate may or may not be avulsed from the proximal nail fold (Fig. 27-8D).

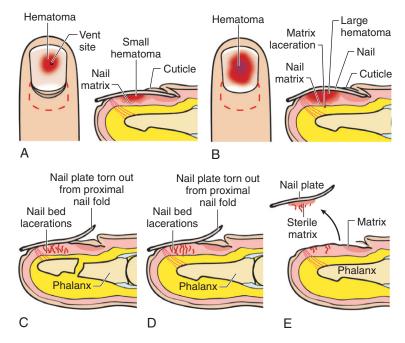

A type V nail bed injury, involving matrix avulsion, can be categorized as follows:

- Avulsed segment available for repair (Fig. 27-8E)
- Small avulsion (less than 2 mm width)
- Large avulsion that requires a split- or full-thickness graft from adjacent finger or toe donor site

# **TREATMENT GUIDELINES**

Type I injuries often go untreated or may benefit from decompression if throbbing pain occurs when the hematoma is small.

Type II injuries involve nail removal and suture repair of the nail matrix. Replace the nail plate as a template into the proximal and lateral nail folds, and anchor with 5-0 nylon sutures through the

**Figure 27-8 A,** Type I nail bed injury: small hematoma. **B,** Type II nail bed injury: large hematoma (>30%) with likely matrix injury. **C,** Type III nail bed injury with phalangeal fracture. **D,** Type IV nail bed injury: extensive matrix injury with intact phalanx. **E,** Type V nail bed injury with matrix avulsion. This particular matrix avulsion shows an avulsed segment available for repair.

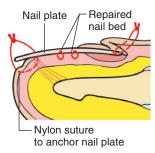

Figure 27-9 Repair of type II injury with nail reattached. The nail bed is repaired and the nail plate or substitute is anchored proximally and distally.

distal nail and hyponychium to prevent accidental removal (Fig. 27-9).

A careful search of the nail fragments should be undertaken to find segments of nail bed that can then be removed carefully with a small elevator and reattached to the nail bed as a free graft to reapproximate the original undamaged nail bed. Again, the intact nail plate or the silicone sheet is used to contour and protect the nail bed during the healing stage.

With *type III* injuries, remove the nail. Stabilize unstable or displaced fractures with small K-wires. Repair the viable matrix with absorbable suture and replace the nail for splinting (Fig. 27-10). If the nail is unavailable or unusable, create a template from sterile silicone sheeting (0.020 inch) and secure in the place of the nail plate.

If the fracture is nondisplaced at the time of the x-ray examination but is so unstable when examined surgically that it cannot be trusted to remain in anatomic position, it must be stabilized with K-wire fixation. Any inadvertent displacement of the dorsal phalangeal cortex during the healing leads to nail bed irregularities and resultant deformed fingernails. The previous principles of repair apply, and serial radiographs are required to verify position of bone fragments and to observe for indication of osteomyelitis. As in other open fractures, prophylactic antibiotics are required until indication of proper wound healing is demonstrated.

With *type IV* injuries, remove the nail and carefully repair the epithelial fragments. This may involve trimming some severely traumatized fragments with very minimal débridement because the nail plate will hold the fragments down into a vascular bed and contour them to heal with the nail bed.

With type V injuries, perform the following:

- With an available avulsed segment, carefully remove it from the nail plate and reattach to the nail bed with a 6-0 or 7-0 absorbable suture.
- Small avulsions (<2 mm wide) may be closed primarily if the nail bed can be undermined with a small elevator and the tissue

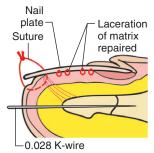

Figure 27-10 Repair of type III injury. The unstable fracture is stabilized, the matrix repaired, and the nail plate secured by nylon suture.

- closed without tension through the use of a 6-0 or 7-0 absorbable surure.
- Larger avulsions require split- or full-thickness grafts from adjacent fingers or toes (see Shepard, 1990a and 1990b).

As mentioned previously, with an avulsed nail bed, look carefully for remnants of the nail bed on large pieces of the nail plate that may accompany the patient. Ask family members or coworkers to look for any amputated fingertips, which may provide needed tissue for the nail bed reconstruction. Sometimes a fingernail and part of the nail bed may still be inside a glove that was worn at the time of injury. If an adjacent finger was amputated or is otherwise irreparable, it may serve as a donor for a full- or partial-thickness nail bed graft for the defect in question. A small defect may be repaired with a small split-thickness graft from an undamaged segment of the involved nail. In larger defects a split-thickness graft from the sterile matrix (do not include the germinal matrix) of the great toe can be used. After removal of the great toenail, use a sterile surgical blade with a thick graft sawing motion to shave approximately 0.014 inch from the nail bed (it is preferable to cut too thin than too thick). Carefully sew the graft in place with fine absorbable sutures, reapply the nail or other template, and secure in place when properly positioned to maintain the proximal and lateral folds in an open

In general, consider perioperative antibiotic use for type III, IV, and V injuries, including distal amputations. Verify that tetanus status is up to date because many of these wounds are grossly contaminated.

#### LATE RECONSTRUCTION OF THE NAIL MATRIX

Delayed reconstruction efforts are frequently associated with disappointment for the patient and the physician. Patients must know up front that odds of a major improvement after surgery are very guarded, and it is possible for the nail to look even worse regardless of best efforts and surgical technique.

- Nail ridges can result from either a scar below the nail bed or a
  fracture healing with a prominence on the dorsal phalangeal
  surface. Correction requires smoothing of the healed bone surface
  and removal of the scar tissue. The defect created by the scar
  removal must be closed either by undermining and direct approximation or by grafting, as mentioned previously.
- Split nails can result from a ridge or longitudinal scar in the germinal or sterile matrix. Resection of the scar in the sterile matrix and use of a free graft, if primary closure is impossible, may be helpful. Use of the proximal eponychial incisions to visualize and graft the germinal matrix may provide some improvement. Some authors advocate use of the second toe as a donor rather than the great toe to avoid cosmetic alteration of the larger great toenail. Use a germinal matrix graft of similar size and shape to fill the resected scar site, as a free graft.
- Nonadherence of the nail is caused from scars in the sterile matrix.
   Resection of the scar and replacement with a free split- or full-thickness matrix graft provides the best results.

# NAIL PLATE, NAIL BED, AND NAIL MATRIX BIOPSY

Steven E. Roskos

Nail biopsy is a simple procedure that can be used to diagnose tumors, inflammatory diseases, and infections of the nail. *Nail plate* biopsy is the simplest of the nail biopsies and is useful for diagnosing proximal subungual onychomycosis as well as distinguishing melanoma from other types of nail pigmentation. *Nail bed* biopsy is helpful in diagnosing many disorders, including psoriasis, lichen planus, squamous cell carcinoma, melanoma, and subungual epidermoid inclusions. *Nail matrix* biopsy is used to distinguish between benign pigmented streaks (longitudinal melanonychia) and melanoma.

The presence of melanocytes in the germinal tissue of the nail matrix makes this a possible site for development of melanoma. Primary subungual melanomas frequently appear as pigmented bands or streaks in the nail plate, and they account for up to 3.5% of all cutaneous malignant melanomas (15% to 20% in blacks). Distinction between the numerous benign causes of pigmented streaks (trauma, malnutrition, and normal occurrence in many blacks and Asians) and malignant lesions is frequently difficult. Biopsy is often recommended to confirm the diagnosis.

# **ANATOMY**

The *nail plate* is the hard, translucent structure composed of keratinized squamous cells, commonly called the "nail" itself. The *nail bed* refers to the softer tissue beneath the nail that provides germinal tissue for the nail plate and to which the nail plate is attached (Fig. 28-1). The nail matrix lies beneath the proximal nail fold and synthesizes 90% of the nail plate.

#### **INDICATIONS**

- Thickened, distorted nail plate with a negative evaluation for fungal infection (potassium hydroxide [KOH] scraping, culture)
- Longitudinal pigmented linear streak in the nail plate suspect for malignancy
- Tumor of the nail bed
- Subungual hyperkeratosis
- Diagnosis of disorders such as psoriasis and lichen planus

# **CONTRAINDICATIONS**

- Allergy or sensitivity to local anesthetics (see Chapter 4, Local Anesthesia)
- Bleeding diathesis or uncontrolled anticoagulation therapy (no need to stop warfarin, aspirin, or clopidogrel)

# **EQUIPMENT**

- Antiseptic (chlorhexidine, povidone-iodine, or alcohol)
- Sterile gloves

- 3-mm disposable skin biopsy punch
- Local anesthetic (e.g., 1% or 2% lidocaine) without epinephrine
- 27-gauge needle (for toes) or 30-gauge needle (for fingers)
- Sterile scissors with straight blades (or a narrow Locke periosteal elevator)
- Sterile rubber band, small Penrose drain, or Ellman disposable digit tourniquet
- Two sterile, straight hemostats
- 5-0 or 6-0 nylon suture
- Needle driver
- No. 15 scalpel (for nail matrix biopsy)
- Fine sterile scissors with curved blades (for nail matrix biopsy)
- Steri-Strips (for nail matrix biopsy)
- Tissue forceps (for nail matrix biopsy)
- Xeroform gauze
- Sterile gauze and tubular gauze dressing
- Antibiotic ointment (Bacitracin or Polysporin)
- Adhesive bandage or an adhesive wrap like Coban or Co-Flex tape
- Suture scissors
- Sterile specimen container filled with 10% formalin (for histology)
- Sterile specimen container without formalin (for fungal culture)

# **PRECAUTIONS**

When sampling the nail matrix, be careful not to damage the proximal matrix. Most linear melanomas (95%) originate from the distal matrix. Biopsies of the distal nail matrix are very unlikely to produce permanent scarring because this part of the matrix produces the ventral portion of the nail plate. Biopsies of the proximal nail matrix will usually cause a permanent nail plate abnormality in the form of a longitudinal fissure. For pigmented streaks less than 3 mm wide, punch biopsy as described in this chapter is an adequate technique. Larger lesions require more extensive excision and are more likely to cause nail deformity.

# PREPROCEDURE PATIENT EDUCATION

It is important to explain to the patient what information you hope to gain from the biopsy and how it will affect treatment decisions. Explain that a biopsy is not guaranteed to produce an accurate diagnosis. Describe the procedure in detail, including the anesthesia. Make sure the patient understands the risks, which include bleeding, distortion of the nail during regrowth, infection, onycholysis (separation of nail from nail bed), permanent nail abnormality, and scarring. The patient should be given an opportunity to read the patient education handout and the consent form before signing it (see patient education and patient consent forms online at www. expertconsult.com).

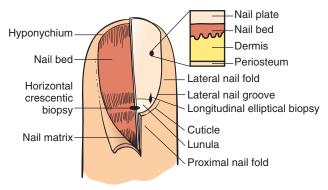

Figure 28-1 Anatomy of the nail, dorsal view. Also shows possible shapes for obtaining a nail biopsy.

# **TECHNIQUE**

# Nail Plate (Nail) Biopsy

- 1. Soak the affected digit and nail in warm water for 10 minutes to soften the nail plate.
- 2. With steady pressure, hold the punch perpendicular to the nail; rotation of the punch will produce a round biopsy specimen without pain. No anesthetic is required.
- 3. Elevate the biopsy sample and lyse the underlying nail bed tissue with the scissors or scalpel.
- Place the specimen in a sterile container if it is being sent for fungal culture, or a formalin-filled container if it is being sent for histology or periodic-acid Schiff (PAS) staining.

# **Nail Bed Biopsy**

- Soak the digit in warm water for 10 minutes to soften the nail plate.
- 2. Prepare the patient's hand with antiseptic.
- 3. Perform a distal wing block or a digital block using 2% lidocaine without epinephrine (Fig. 28-2; see Chapter 8, Peripheral Nerve Blocks and Field Blocks).
- Apply a tourniquet to decrease bleeding at the site and allow easier removal of specimen.

- 5. Partially remove the nail plate according to the procedure outlined in Chapter 29, Ingrown Toenails.
- 6. When the affected nail bed has been exposed, use a 3- or 4-mm punch to obtain the biopsy specimen as close as possible to the proximal origin of the pigmentation. However, there is a higher chance of a deformed nail if the biopsy is obtained from the root portion of the nail under the proximal nail fold. The biopsy specimen should be 2 to 3 mm in thickness. Alternatively, small elliptical excisions can be made (see Fig. 28-1 and Chapter 32, Skin Biopsy).
- 7. Close the biopsy site with one or two 5-0 or 6-0 nylon sutures oriented along the longitudinal plane.
- 8. Remove the tourniquet.
- 9. Apply a dressing of antibiotic ointment and sterile gauze.

# **Nail Matrix Biopsy**

- 1. Soak the digit in warm water for 10 minutes to soften the nail plate.
- 2. Prepare the patient's hand with antiseptic.
- 3. Perform a digital block using lidocaine without epinephrine (see Fig. 28-2).
- 4. Apply a tourniquet to decrease bleeding at the site and allow easier removal of specimen.
- 5. Make two lateral incisions in the proximal nail fold at an angle of 45 degrees using a no. 15 scalpel (Fig. 28-3).
- 6. Use a periosteal elevator to detach the proximal nail fold from the nail plate. This should expose the entire nail plate and allow you to visualize the origin of the pigmented streak (longitudinal melanonychia). The nail plate can be left in place (Fig. 28-4) or reflected (see Fig. 28-3).
- 7. Place a 3-mm punch against and perpendicular to the nail plate directly over the origin of the pigmented streak (see Fig. 28-4A).
- 8. Rotate the punch between the thumb and forefinger.
- 9. After scoring the nail, check to be sure the origin of the band is entirely encompassed by the punch.
- Reapply the punch and continue to rotate until you contact bone.
- 11. Gently lyse adhesions to the bone using fine curved scissors (see Fig. 28-4B).
- 12. Gently remove the specimen using the scissors or tissue forceps and place the whole specimen, including nail plate (which may be stuck inside the punch), in the formalin-filled specimen container. Be careful not to crush the specimen.

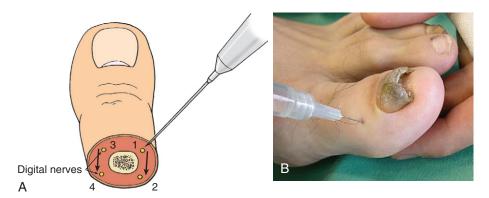

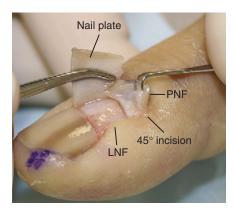

Figure 28-2 A, Ring block technique for digital nerve block. I, Raise a wheal at the dorsal surface of the base of the digit. 2, Direct the needle toward the plantar surface, delivering I mL of anesthetic to the extensor and I mL to the plantar branches of the digital nerve. 3, Perform a second puncture at the corresponding site of the other side. 4, Advance the needle in the plantar direction to allow delivery of I mL of anesthetic to each branch of the digital nerve. A minimum of 4 mL of anesthetic is used. Also see Chapter 8, Peripheral Nerve Blocks and Field Blocks. B, Administering a distal wing block. Insert needle 5 to 8 mm proximal and lateral to the junction of the proximal nail fold and lateral nail fold. Inject anesthetic until it progresses as far as possible down the nail fold toward the tip of the digit, distending and blanching the lateral nail fold. This has the appearance of a "wing." Repeat on the other side of the nail. If necessary, inject at other already anesthetized areas around the nail until the entire digital tip is swollen and white. (B, From Richert B: Basic nail surgery. Dermatol Clin 24:313–322, 2006.)

**Figure 28-3** Proximal nail fold (PNF) is reflected (with skin hook) and proximal nail plate is partially avulsed and reflected (with hemostat), exposing the nail matrix. The nail plate can be reattached with nylon sutures to the lateral nail fold (LNF). (From Jellinek N: Nail matrix biopsy of longitudinal melanonychia: Diagnostic algorithm including the matrix shave biopsy. J Am Acad Dermatol 56:803–810, 2007.)

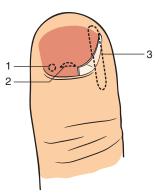

- 13. Apply Steri-Strips to the two lateral incisions and the defect in the nail plate.
- 14. Remove the tourniquet.
- 15. Dress the site as described in the next section.

The possible shapes and types of biopsies are summarized in Figure 28-5.

**Figure 28-4 A,** Nail matrix biopsy with nail plate in place. The proximal nail fold is reflected (with skin hooks, optional) while punch is held perpendicular to nail plate over origin of linear pigmentation (nail plate has not been reflected in this figure). Scarring is more likely to occur if the germinal matrix is sampled. **B,** Removing punch sample. Gently lyse adhesions to the bone using fine curved scissors, held nearly perpendicular to the nail plate. (From Jellinek N: Nail matrix biopsy of longitudinal melanonychia: Diagnostic algorithm including the matrix shave biopsy. J Am Acad Dermatol 56:803–810, 2007.)

**Figure 28-5** Alternative biopsy techniques. I, Punch biopsy of nail matrix; 2, transverse biopsy of nail matrix, used for longitudinal pigmented streaks between 3 and 6 mm; 3, longitudinal nail biopsy for lateral nail pigmentation. (From Braun RP, Baran R, Le Gal FA, et al: Diagnosis and management of nail pigmentation. | Am Acad Dermatol 56:835–847, 2007.)

#### POSTPROCEDURE MANAGEMENT

- 1. Apply topical astringent (e.g., Monsel's solution), remove the tourniquet, and control bleeding with pressure.
- 2. Place a bulky dressing of gauze over the surgical site (except for the nail plate biopsy, where a simple adhesive bandage may be applied over antibiotic ointment). Use multiple 2 × 2 gauze pads, folded in half and wrapped over the nail transversely and longitudinally. Secure these with significant pressure and tape or adhesive dressing.
- 3. Observe the patient for 10 to 15 minutes. If blood soaks through the bandage, apply pressure to the lateral digital arteries and remove the bandage. Apply a clean, dry gauze pressure dressing while holding pressure on the arteries.

# POSTPROCEDURE PATIENT EDUCATION

The patient should keep the limb elevated until the next day to decrease throbbing. Acetaminophen or ibuprofen may be used for pain. If the patient experiences increasing pain several hours after the procedure, the dressing may be acting as a tourniquet and should be removed. Otherwise, the patient should leave the dressing in place for 24 to 48 hours, after which he or she may remove the dressing, wash the wound with a 1:1 mixture of hydrogen peroxide and tap water or simple soap and water, and apply a large adhesive bandage over a gauze and antibiotic ointment. The patient should repeat this procedure two to three times daily until the area has healed.

#### **NAIL BIOPSY ENCOUNTER FORM**

See Encounter Form, Nail Biopsy, online at www.expertconsult.com.

#### **COMPLICATIONS**

- Bleeding
- Infection
- Distortion of nail with regrowth and permanent nail abnormality (the greatest concern if the germinal matrix is sampled)
- Onycholysis (separation of the nail plate from the nail bed)
- Scarring

# **CPT/BILLING CODES**

- 11730 Avulsion of nail plate, partial or single
- 11732 Avulsion, each additional
- 11755 Biopsy nail unit, any method
- 11765 Wedge excision of skin of nail fold (e.g., for ingrown toenail)

#### **ICD-9-CM DIAGNOSTIC CODES**

- 110.1 Dermatophytosis of nail
- 117.9 Other and unspecified mycoses
- 172.6 Malignant melanoma of skin, upper limb, including shoulder
- 172.7 Malignant melanoma of skin, lower limb, including hip
- 173.6 Other malignant neoplasm of skin, upper limb, including shoulder
- 173.7 Other malignant neoplasm of skin, lower limb, including hip
- 216.6 Benign neoplasm of skin, upper limb, including shoulder
- 216.7 Benign neoplasm of skin, lower limb, including hip
- 239.2 Neoplasm of unspecified nature of bone, soft tissue, and skin
- 703.8 Other specified diseases of nail (besides ingrowing nail); includes dystrophia unguium, hypertrophy of nail, koilonychia, leukonychia (punctata) (striata), onychauxis, onychogryphosis, onycholysis
- 703.9 Unspecified disease of nail

# INGROWN TOENAILS

Madelyn Pollock

Ingrown toenails usually present with pain, redness, swelling, and sometimes discharge. It is not uncommon for patients to have attempted self-remedies. Often, the irritation is long-standing enough to cause granulation tissue to form. The great toe is virtually the only toe involved, and either the medial or lateral border of the nail may be affected.

Figure 29-1 is an algorithm for the suggested treatment of an ingrown toenail.

Removal of the toenail, either partial or total, remains the definitive treatment for bothersome ingrown nails. For recurrent episodes, ablation of the germinal matrix tissue can be used to prevent regrowth of the nail. Permanent destruction can be effected using chemicals or radiofrequency energy.

#### **ANATOMY**

Figure 29-2 illustrates the nail bed anatomy.

#### **INDICATIONS**

- Onychocryptosis (ingrown nail)
- Onychomycosis (fungal infection of the nail) with significant pain; without medical treatment, however, the fungus will recur
- Chronic, recurrent paronychia (inflammation of the nail fold)
- Onychogryposis (deformed, curved nail)

For a first occurrence, it is reasonable to remove only the offending portion of the nail and allow regrowth while educating the patient to correct all offending practices such as overtrimming nails and wearing tight-fitting shoes. If an ingrown nail recurs, permanent ablation of the portion of nail matrix causing the problem is indicated.

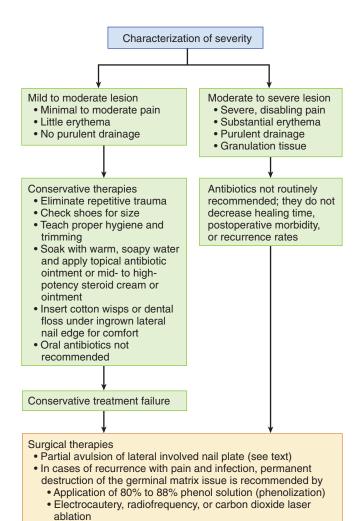

#### **CONTRAINDICATIONS**

- Allergy to local anesthetics (see Chapter 5, Local and Topical Anesthetic Complications).
- Bleeding diathesis.
- Diabetes mellitus and peripheral vascular disease are relative contraindications and should be considered on a case-by-case basis.
- Pregnant patients should not have phenol ablation.

# **EQUIPMENT AND SUPPLIES**

- 5- or 10-mL syringe with long (1½-inch) needle (25 or 27 gauge).
- Local anesthetic generally without epinephrine (e.g., 2% lidocaine with or without sodium bicarbonate buffer to decrease the sting; see Chapter 4, Local Anesthesia). Recent research does not confirm the previous concerns that epinephrine might cause excess vasoconstriction in the digits. However, with patients at high risk, such as those with long-standing diabetes or severe peripheral vascular disease, it might be best to avoid it.
- Narrow Locke periosteal elevator (nail elevator; Fig. 29-3).

- Sterile scissors with straight blades (or an English nail splitter [Fig. 29-4] or miniblade with wedge tip).
- Wide rubber band, small Penrose drain, donut digital tourniquet (Ellman Corp.; Fig. 29-5), or a portable blood pressure cuff (tourniquets are optional but very helpful).
- Two straight hemostats.
- Silver nitrate sticks for cautery of granulation tissue (optional).
   Best to curette this tissue off with a reusable dermal curette.
- Alcohol swabs.
- Povidone-iodine (Betadine) solution.

**Figure 29-1** Algorithm for a suggested approach to the patient with an ingrown toenail. (Modified from Heidelbaugh JJ, Lee H: Management of the ingrown toenail. Am Fam Physician 79:303–308, 2009.)

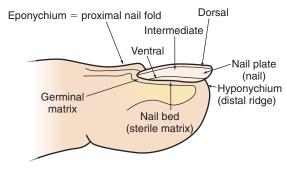

Figure 29-2 Nail bed anatomy and terminology. Also see more details in Chapter 27, Nail Bed Repair.

- Monsel's solution to control any possible bleeding after the tourniquet is removed.
- Sterile gauze and tubular gauze dressing.
- Antibiotic ointment (Polysporin or Bacitracin).
- Phenol solution (88%) and isopropyl alcohol for permanent ablation of the nail, if desired.
- As an alternative to phenol, the Ellman Surgitron (radiofrequency unit) with specially designed, Teflon-insulated matrix ablation tips (less inflammation and excellent results; see Chapter 30, Radiofrequency Surgery [Modern Electrosurgery]).

# PREPROCEDURE PATIENT EDUCATION AND CONSENT

See the patient education form online at www.expertconsult.com.

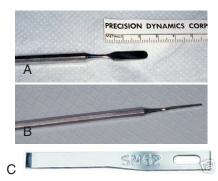

A signed consent is not mandatory but the patient must be well informed of the procedures and the intended outcome. A patient education handout that explains the nature of ingrown nails is helpful. Before beginning the procedure, be sure the patient understands that providing anesthesia is uncomfortable, but after that there should be no pain. There is no guarantee that removing the portion of ingrown nail will resolve the problem, but generally it will if the nails are cared for properly afterward. The major benefit to removing the toenail (or a portion of it) is pain relief, with the secondary benefit of allowing the body to heal the inflamed area.

#### **PROCEDURE**

**NOTE:** Nonsterile gloves may be used in this procedure.

#### Removal of Partial or Full Nail

1. With the patient in the supine position, *prepare* the toe with Betadine. If the patient has significant discomfort, anesthesia (step 2) can precede this step for patient comfort.

**Figure 29-3** Locke periosteal elevator. **A,** Front view. **B,** Side view. **C,** Miniblade with wedge tip. (Courtesy of John L. Pfenninger, MD, The Medical Procedures Center, PC, Midland, Mich.)

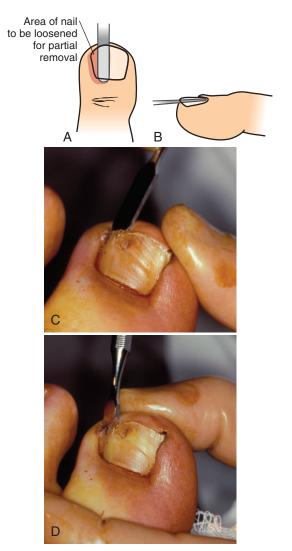

**Figure 29-4** Nail splitter. **A,** Flat jaw on bottom. **B,** Beveled jaw on top. (Courtesy of John L. Pfenninger, MD, The Medical Procedures Center, PC, Midland, Mich.)

- 2. Administer a digital block as described in Chapter 8, Peripheral Nerve Blocks and Field Blocks.
- 3. Apply a tourniquet if desired. Options include the following:
  - Use a straight hemostat to firmly secure a wide rubber band or Penrose drain around the base of the toe.
  - Apply a blood pressure cuff at the calf so it will not affect the operative field. To use this method, place the cuff around the calf, elevate the foot to about a 45-degree angle at the hip, and, after 1 to 2 minutes of elevation, raise the cuff pressure to above systolic, lock the cuff it so it stays inflated, and then lower the foot to the operative field. Maintain the pressure until the procedure is completed.
  - The Ellman donut tourniquets (see Fig. 29-5) are disposable and come in various sizes. After the procedure, simply cut them with scissors to remove them.
- 4. Identify the portion of the nail to be removed, which is at least 20% to 25% of the nail.
- 5. When anesthesia is achieved (5 to 10 minutes), loosen and lift the nail to be removed from the nail bed by using the flat, rounded blade of the scissors, a single jaw of a straight hemostat, or a narrow periosteal elevator. The elevator works best to decrease the likelihood of injury to the nail bed (see Fig. 29-3). Introduce

**Figure 29-5** The Ellman digital tourniquet. (Courtesy of John L. Pfenninger, MD, The Medical Procedures Center, PC, Midland, Mich.)

**Figure 29-6 A,** Periosteal elevator advanced all the way under the proximal nail fold. **B,** Lateral view. Advance with upward pressure on the nail with forward motion until more pressure is felt under the nail fold. **C,** Inserting the elevator. **D,** The instrument has been fully inserted, freeing up the lateral portion of the nail from the nail bed. (**C** and **D,** Courtesy of John L. Pfenninger, MD, The Medical Procedures Center, PC, Midland, Mich.)

and advance the instrument with continued upward pressure against the nail plate and away from the nail bed to minimize injury and bleeding (Fig. 29-6). It is important to completely free the proximal nail at its base under the nail fold to allow removal and to expose the germinal tissue of the nail bed. Push forward gently—the elevator moves easily when under the nail. Resistance will be felt when the proximal end of the nail plate has been loosened sufficiently. Release the entire nail plate in this fashion if the entire nail is to be removed.

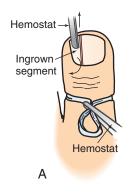

- 6. For a partial nail removal, scissors or a nail splitter (see Fig. 29-4) should be used to completely split the nail 5 to 6 mm in from the lateral or medial margin in a longitudinal direction (Fig. 29-7). A miniblade with a wedge at the tip also works well. Include the base of the nail. This requires introducing your cutting instrument beneath the proximal nail fold. Take care to protect the nail fold from damage when making this part of the incision.
- 7. Grasp that portion of the nail to be removed lengthwise with a straight hemostat and remove it, using a steady pulling motion with a simultaneous upward twist of the hand toward the affected side (Fig. 29-8). This twisting action ensures that the nail will be

**Figure 29-7** Using the nail splitter to "cut" through the nail. Flat jaw is down, beveled side is up. (Courtesy of John L. Pfenninger, MD, The Medical Procedures Center, PC, Midland, Mich.)

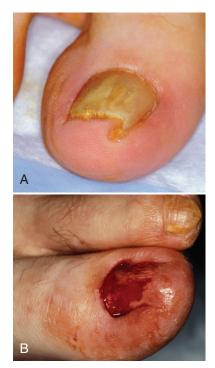

rolled out from beneath the affected nail margin instead of rolling over it. If the entire nail is to be removed, the nail may be removed in two halves or in its entirety after a thorough loosening and lifting of the nail. In removing the entire nail, the forceps should apply lift and distal traction on the nail as it separates from the nail bed. Indications for total removal include onychomycosis that can cause painful pincer nails or perhaps having both the medial and lateral aspects of the nail ingrown (Fig. 29-9).

- 8. Remove all granulation tissue by grasping with hemostats and pulling. Light curettage with a reusable dermal curette (not as sharp as the disposables) removes any residual tissue from the nail groove. Without a tourniquet there will be significant bleeding during this portion of the procedure, especially if there is significant granulation tissue. Application of silver nitrate or Monsel's solution to the exposed nail bed will control bleeding and, with silver nitrate, discourage persistence of granulation tissue.
- If ablation is to be performed, complete that portion at this step before the tourniquet is removed and the wound dressed (see later discussion).
- 10. Remove any tourniquet used.
- 11. Observe the area for hemostasis, using pressure as necessary. When hemostasis is obtained, dress with antibiotic ointment, non-adherent gauze pad, and tube gauze (Fig. 29-10).

**Figure 29-8** Technique for nail removal after nail has been elevated and split. **A** and **B**, Grasp that portion of the nail to be removed lengthwise with a straight hemostat, and remove it using a steady pulling motion with a simultaneous upward twist of the hand toward the affected side. **Figure 29-9** Complete removal of the toenail. **A,** Onychomycosis. **B,** Appearance after the nail has been removed. (Courtesy of John L. Pfenninger, MD, The Medical Procedures Center, PC, Midland, Mich.)

# Nail Bed Ablation (Matrixectomy)

If recurrent regrowth of the toenail with resulting pain or infection occurs, permanent ablation of the germinal tissue is recommended (matrixectomy).

#### Phenol Chemical Method

- Remove total or partial nail as described previously. The area must be dry and not bleeding. Remove all granulation tissue.
- 2. Sponge the exposed nail bed dry with cotton swabs and then cauterize the germinal tissue, including that under the nail fold, by application of phenol on a cotton swab to the nail bed tissues (Fig. 29-11). It is important to achieve good hemostasis before this step so that the tissue is dry. *Use caution to avoid phenol contact with normal skin*. A skin hook can be helpful in elevating the skin fold from the nail matrix. Hold the phenol-dampened cotton swab in place for 3 minutes. Three separate 60-second applications with drying of the surface in between is also reported to be effective. The tissue will pale or "gray" at the area of application.

**Figure 29-10** A compression dressing is applied after most toenail procedures. (Courtesy of John L. Pfenninger, MD, The Medical Procedures Center, PC, Midland, Mich.)

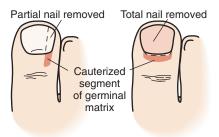

Figure 29-11 Area of nail bed to be cauterized in partial (*left*) and total permanent nail removal (matrixectomy) (*right*).

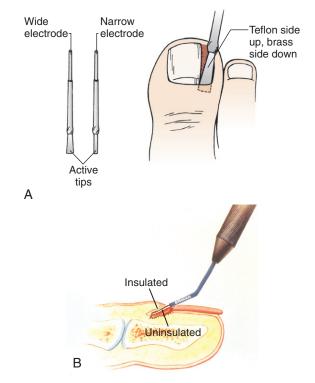

3. After 3 minutes, drip 70% isopropyl alcohol into the nail groove and swab the area to neutralize the phenol.

#### Radiofrequency Method

See Chapter 30, Radiofrequency Surgery (Modern Electrosurgery).

The radiofrequency method of ablation is quick and easy. Although formal studies have not been performed, it is thought that radiofrequency causes markedly less pain, swelling, and discharge than other methods. It is difficult to control liquid agents, and they tend to destroy more tissue than desired.

- 1. Remove whole or partial nail as described previously.
- 2. Place antenna lead under the heel of foot.
- 3. Turn unit to "Hemo-part rect" (hemostasis/coagulation setting) and set the power at 2 to 3.
- 4. Insert wide or narrow insulated matrixectomy tip over nail matrix, under the eponychium as far as it will go, insulated side up (Fig. 29-12). These electrodes are insulated with Teflon on one surface to prevent damage to the undersurface of the

**Figure 29-12** Application of nail matrixectomy electrode with Tefloncoated side up: top (**A**) and lateral (**B**) views. The lateral 25% of the nail has been removed.

- proximal nail fold while ablating the nail matrix with the uninsulated surface beneath. A slight upward pressure should be exerted against the undersurface of the nail fold to ensure that no pressure is exerted on the underlying matrix. The field must be free of blood. For proper effect, there should be a slight gap between electrode and matrix.
- 5. Apply power and slowly withdraw the electrode pulling distally. Contact should last for only 1 to 2 seconds, and a sizzling sound should be heard. This step can be repeated once or twice over the same area after a 15-second cooling period. If the entire nail matrix is to be ablated, multiple applications are necessary with side-to-side placements of the electrode; slight overlapping should not be a problem. Caution: two to three passes (maximum) over the same tissue area are sufficient. Avoid overtreatment. The matrix is very thin and bone lies immediately beneath it. Overtreatment can cause burns with prolonged healing times of up to 6 to 8 weeks. It is often easier to use the narrower electrode because the power level can be set lower and it affords better control. Side-by-side applications may then be needed even for partial nail removal.

#### Other Methods

Sodium hydroxide (10% solution) and  $CO_2$  laser are also described in the literature for use in matrixectomy. Sodium hydroxide is applied similarly to phenol and is thought by some to decrease postoperative drainage and speed healing compared with the phenol method. It is not as commonly used in the United States as phenol. The  $CO_2$  laser requires special equipment and training and is usually operated by dermatologists or podiatrists.

When either partial or complete ablation is accomplished apply antibiotic ointment to the nail bed, cover with a sterile gauze pressure dressing, remove the tourniquet, and wrap with a tubular gauze dressing. Coban, CoFlex, and other similar self-adherent dressings provide a comfortable pressure wrap that holds the dressing in place.

#### SAMPLE OPERATIVE REPORT

Informed consent obtained: Yes No
Site (circle one): Left Right Medial Lateral great toe
Anesthesia: Digital block% Lidocaine without epimL
Tourniquet used: Yes No
Nail removal (circle one): Complete Partial
Granulation tissue removed: Yes No Cautery Y
Chem/elect N
Ablation performed: No Yes (Phenol radioablation
[tip wide narrow, setting])
Other
Hemostasis was obtained.
The wound was dressed with antibiotic ointment and covered with

The wound was dressed with antibiotic ointment and covered with a sterile dressing. The patient was given oral and written instructions in postoperative management. The patient tolerated the procedure without complications.

#### **COMMON ERRORS**

- Inadequate anesthesia resulting in patient discomfort. Ensure full
  anesthesia before starting procedure. Anesthetizing the toe generally requires 6 to 10 mL of lidocaine.
- Prolonged use of tourniquet resulting in ischemia. This can be avoided by foregoing use of the tourniquet in patients with possible decreased circulation and limiting the time under tourniquet pressure for all cases.
- Laceration of nail bed during lifting or splitting of the nail. This
  can result in difficult-to-control bleeding at the nail edge and
  scarring, leading to deformity of the nail when it grows back.
  Position any cutting instrument used such that the nail bed is
  protected during the incision. Use of the miniblade (also called

- Beaver or wedge blade), which has no sharp edge on the portion of the blade facing the nail bed, can help.
- Retained portion of nail results in persistent pain after procedure. Avoid this by careful examination of the nail fold and the removed portion of the nail after the procedure. A feathery edge of nail where it abuts the nail growth plate demonstrates that all the nail was removed. If necessary, explore the area and remove retained fragments.

#### **COMPLICATIONS**

- Infections (treat with soaking and appropriate antibiotics)
- Bleeding (generally controlled with pressure)
- Regrowth of nail and return of symptoms (regrowth rate after phenol cauterization is 4% to 25%; for radiofrequency, <5%)</li>
- Excessive tissue destruction with radiofrequency unit, leading to prolonged healing time and possible osteomyelitis

# POSTPROCEDURE PATIENT EDUCATION AND MANAGEMENT

The foot should be rested and preferably elevated during the first 12 to 24 hours. Because phenol ablates the nerve endings of the nail plate, pain should be absent when it is used. There is minimal pain with the radiofrequency unit. Nonsteroidal anti-inflammatory drugs or acetaminophen may be taken for discomfort.

The dressing should be changed in 12 to 24 hours, at which point ambulation can be encouraged; however, vigorous exercise should be avoided for 1 week. The toe should be washed with soap and water at least twice daily (depending on soiling) until healed. Topical antibiotic ointment should be applied and the area kept clean until healed. Tell the patient to expect a sterile exudate from the nail bed for several weeks. Explaining that the wound will "heal like a burn" can help patients understand that the exudate is not an indication of infection. Emphasize proper nail hygiene to prevent further recurrences (Fig. 29-13).

# RADIOFREQUENCY SURGERY (MODERN ELECTROSURGERY)

John L. Pfenninger

Radiofrequency (RF) surgery—modern electrosurgery—has become a versatile tool for the primary care physician in dermatologic, surgical, and gynecologic applications. It is both time and cost effective, and it provides efficacious treatment for a multitude of lesions. Appropriate selection of waveform and current intensity allows excision (cutting), cutting and coagulation (blend), pure coagulation (hemostasis), or fulguration. Tissue either can be removed delicately with excellent cosmetic results or can be totally ablated. The electrosurgical unit (ESU) can be used for treatment of both benign and malignant lesions.

This chapter is based on the Ellman Surgitron (Ellman International, Inc., Hewlett, NY), a portable generator that creates high-frequency current of 3.8 to 4.0 MHz, which is comparable to the radiowave frequency for broadcasting (Figs. 30-1 and 30-2). ESU

wave frequency for different brand models can vary from 500,000 to 4 million cycles (4.0 MHz) per second. All units can be used with a multitude of electrode tips for a large variety of applications. With the advent of the loop electrosurgical excision procedure (LEEP) in the 1990s, many companies introduced units into the market. Unless otherwise noted, discussion here will be in reference to the Ellman Surgitron because it is widely adapted to many dermatologic procedures. The reader can generalize the discussion to most other units quite readily.

There is a choice of three waveform outputs plus a fulguration current (four modes). By changing waveforms, practitioners obtain different effects. The settings of the Ellman unit are described as filtered fully rectified, fully rectified, and partially rectified. These correspond with a pure cutting effect (90% cutting, 10% coagulation),

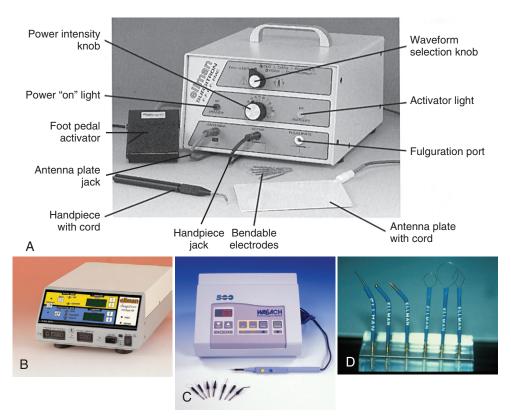

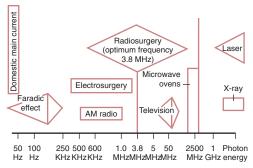

Figure 30-1 A, Ellman Surgitron radiofrequency unit with foot pedal, antenna plate, and hand wand tip holder. A variety of electrode tips are lying above the white antenna plate. B, Ellman Dual Frequency IEC II. C, The Wallach Q500 electrosurgical unit with finger control handpiece and a variety of electrodes. D, Typical electrodes (Ellman) for skin electrosurgery (*left to right*): vari-tip cutting wire; ball electrode and pointed electrode for cautery or fulguration; small and large loops; diamond-shaped electrode. (A, B, and D, Courtesy of Ellman International, Inc., Hewlett, NY. C, Courtesy of Bruno Ratensberger.)

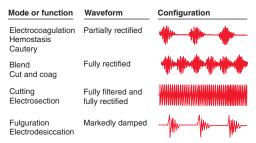

**Figure 30-2** Comparison of uses and effects of various electrical frequencies. (Courtesy of Ellman International, Inc., Hewlett, NY.)

a *blended* current to allow 50% cut and 50% coagulation, and a 90% *coagulation* (hemostasis) effect, respectively. A separate outlet also provides a spark-gap fulgurating current (referred to as *hyfrecation*) for very superficial cautery (Fig. 30-3).

Advantages of using RF technique include rapidity of treatment, a nearly bloodless field, minimal postoperative pain, and rapid healing. Local anesthetic is used except in rare instances. Because the frequency is so high, the current from this unit passes through the body without causing painful muscle contractions or nerve stimulation (Faraday effects). Radiosurgery using the cutting wave cuts without pressure, needing only a feather-like touch, and thus minimizes tissue damage. The tissue damage that does occur is very superficial and comparable with that of proper laser use. This is in contrast to true cautery, which causes damage similar to third-degree burns. In addition, radiosurgery avoids the risk of electrical burns to the patient. Instead of a ground plate, an antenna is used to focus the "radio waves." In contrast to other electrical units, this antenna does not have to be in contact with a patient's skin; instead, it only needs to be under the patient near the operating field. (Most ESUs with lower-frequency output, however, do require true grounding pads or plates, so the manufacturer's recommendations must be followed.)

The high-frequency energy of this unit is concentrated at the tip of each electrode. During each procedure, the electrode itself remains cold; however, the highly concentrated electrical energy creates molecular energy inside each cell it contacts, thereby creating intracellular heat and actually vaporizing the cell, much as a laser does. The amount of heat generated depends on the amount of time the tip is in contact with the tissue, the size of the electrode, the power setting, the type of waveform selected, and the wave frequency. Higher frequency means less contact time, finer wire, less power, a more "cutting" waveform, and less tissue damage.

High-frequency electrosurgery is now replacing many laser applications because of the minimal tissue damage, low cost of equipment, minimal maintenance, ease of treatment, and excellent long-term results. It has replaced most laser applications for the gynecologic treatment of dysplasia (conization) and condylomata. It is now also being used for blepharoplasties, radioassisted uvulo-

palatoplasty (RAUP) for snoring, spinal procedures, skin tightening (dual-frequency unit), and many more applications.

#### **INDICATIONS**

Radiofrequency surgery can be used for a variety of skin and mucosal lesions. It is especially helpful when good cosmetic results are essential. It is also very helpful in well-perfused areas like mucosa and the anal area because the "cut and coag" setting can be used to control the bleeding. Common uses and lesions treated are listed in Box 30-1.

#### **CONTRAINDICATIONS**

- Cardiac pacemakers (relative contraindication): Do not work near
  the heart and place the antenna (or grounding) plate well away
  from the heart. Use the least power possible. Activate the handpiece intermittently rather than continuously. The cutting mode
  is the most risky, so avoid it if possible. Use another form of
  treatment if it is an option. The pacers are purportedly "shielded"
  and the current in the ESUs should not affect them, but all things
  are not perfect! Therefore caution is needed. Asystole and tachycardia are potential adverse outcomes.
- Uncooperative patient.

#### **EQUIPMENT**

- Alcohol wipe
- Local anesthetic (e.g., 2% lidocaine with or without epinephrine)
- 1-mL syringe with 30-gauge needle
- ESU
- Electrode tips (depending on procedure performed): reusable or disposable
- No. 15 scalpel blade
- Antenna (or grounding) plate
- Handpiece for tips (unit can be finger-activated from this handpiece if desired)
- Foot pedal to activate handpiece (or use handpiece as above); foot pedal preferred for delicate surgeries
- Smoke evacuator (human immunodeficiency virus [HIV] and human papillomavirus [HPV] have been found in smoke plume)
- Room air purifier or exhaust fan (removes residual odor)
- Moveable cart to hold the ESU, smoker evacuator, tips, and all equipment for the procedures
- Mask
- Nonsterile gloves
- Aluminum chloride for topical control of bleeders (or Monsel's solution if face is not involved)
- Antibiotic ointment
- Band-Aid
- Patient education handout on moist healing (which is essential to obtain optimal results). (See the sample patient education handout available online at www.expertconsult.com.)
- For LEEP supplies, see Chapter 149, Loop Electrosurgical Excision Procedure for Treating Cervical Intraepithelial Neoplasia.

The most common tips used for removal of skin lesions are the large and small loops. The ball electrode is used frequently for coagulation and for ablation of lesions. Special tips are available for matrixectomy (see later discussion and Chapter 29, Ingrown Toenails) and skin tightening (see Chapter 52, Nonablative Radiowave Skin Tightening with the Ellman S5 Surgitron [The Pelleve Procedure]).

Disposable tips are convenient but can be costly. Reusable tips must be free of carbon buildup and shiny to obtain best results. After cleaning and sterilizing, and before repeat use, the tip must be examined. If it is not shiny, the carbon can be removed in several ways:

- Use a 2 × 2-inch piece of fine sandpaper and, using the index finger to support the back side of the loop, rub it over the sandpaper. Turn it over and do the reverse side. Be sure to clean the entire wire loop.
- Purchase the cleaning "blocks" available.
- Place the units in an ultrasonic cleaner.
- Use a moistened piece of 4 × 4 gauze, insert the tip into the folded material, and activate it on the cutting setting, level 5.

When complete, the wire should be shiny (like new). One of the most *common reasons for poor cutting and "stalls"* during RF surgery is "dirty" (carbon-covered) reusable loops, which is avoided if disposable tips are used.

Most ESUs have digital readouts for *wattage* (power intensity). The Ellman simply has an intensity dial labeled 1 to 10. Each unit roughly corresponds to 10 W. For skin surgery a setting of 2 to 4 (20 to 40 W) is usually needed. (As a "default," remember "pure cutting on level 2.")

Use of a *smoke evacuator* is essential. Not only have HPV and HIV been found in smoke plume (no infections have been documented), but the smell of burning flesh is very offensive and the examination room and office can smell for hours afterward.

The dual-frequency unit (Ellman Surgitron DF IEC II; see Fig. 30-1B) is being used with increasing frequency for plastic surgery and neurosurgery applications. Its coagulation potential is much

better and it can coagulate in a "wet" (bloody) field using the bipolar modality. This is achieved through the dual frequencies of 4 MHz for cutting but 1.7 MHz for bipolar coagulation. This unit will not interfere with any nearby electronics or electrical circuits. Other benefits include a higher frequency (4.0 vs. 3.8 million cycles per second) than the original equipment. There is still minimal thermal damage when cutting. It meets national safety codes for operating room use, and it is more user friendly because there is a two-pedal foot switch for cutting or coagulation and a three-button finger switch (for each modality). It has a memory for the most recent settings when turned off, digital power settings, and an audible sound when activated. This unit is significantly more expensive, and whether the benefits warrant the extra cost for the average practitioner remains to be seen. The dual-frequency unit with the special electrodes must be used for skin-tightening procedures. Those considering offering aesthetic procedures in their practice may want to consider this unit.

#### **TECHNIQUE**

Proper technique is accomplished when the loop electrodes pass through the tissue smoothly, like cutting through soft butter. Generally, a motion of 5 to 8 mm/sec is appropriate. If there is excess sparking and smoke, the power setting is too high. If the flow is not smooth, the operator is going too fast, the power setting is too low, the skin is too dry or hyperkeratotic, or the electrode is dirty (debris or carbon buildup). It is important to remember that the least tissue damage occurs with the pure cutting setting. Coagulation causes the most tissue destruction. If cosmetic results are desirable, judicious use of the coagulation setting and using as little power (watts) as possible is important.

The most common use for the RF unit in primary care is removal of elevated skin lesions such as nevi and seborrheic lesions. Commonly, when using a blade to shave off a benign nevus, two things result: bleeding and an irregular surface. As the surgeon tries to smooth out the "highs" in the base of the wound, blood obscures the area. Then, as the blade is used to shave off these highs, too much tissue is removed, leaving "dips." The "lows" (too much tissue removed) and the "highs" (too little) result in adverse outcomes with undesirable scarring. Using the RF technique, both bleeding and an uneven wound base can be avoided. In addition, any focal areas of undesirable residual tissue are removed and the edges can be smoothed for a more pleasing cosmetic result. Because the tissue left behind has minimal thermal damage, healing is quick and scarring is minimized.

The most successful technique for removing lesions appears to be first to "debulk" the majority of the lesion with a no. 15 blade in a shave fashion (see Chapter 32, Skin Biopsy). Then, use the loop electrode on a pure cutting setting of 2 (20 W) to smooth out or vaporize the base of the wound. Pinch the skin around the area to control bleeding, activate the loop, and very superficially pass the tip over/through the tissue, gradually going down until the lesion is smoothed out adequately (Fig. 30-4). This "smoothing out" of the base provides an excellent outcome with rapid healing. The "cutting" setting has 10% coagulation so bleeding is nicely controlled. The tissue is literally vaporized cell layer by cell layer. Healing results are excellent. Another advantage with the method described is that the tissue sent to pathology has no burn artifact.

Some advocate the removal of lesions primarily with the loop only (as opposed to using the blade). Extreme caution is needed! The loop cuts so quickly that it often goes too deep. Even in experienced hands too much tissue may be removed unless the process is very slow and meticulous with only a small amount of tissue removed each time. Do not try to remove all of the lesion with the first pass! The only time the "layered" or "feathering" removal technique is recommended is for larger condylomata (Fig. 30-5).

Another advantage of shaving the lesion first with a blade is that a good specimen is available for pathology. If the loop is used, there

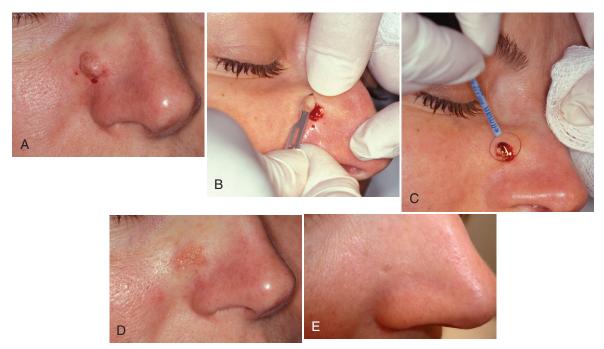

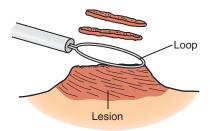

Figure 30-4 Preferred technique for removal of raised lesions with a broad base. **A,** Nasal nevus after infiltration with lidocaine. **B,** Shave the lesion with a no. 15 blade. Remove most of the lesion, being careful not to go too deep. **C,** Smooth out the base and control bleeding with a large loop electrode (cutting, 2). "Sculpt" the final result. Proceed very superficially and literally remove a few cell layers at a time to blend the edges. **D,** Appearance on completion of removal. **E,** Appearance 2 years after removal. (Courtesy of The Medical Procedures Center PC, Midland, Mich.)

will always be some coagulation artifact, albeit minimum. If total vaporization or the coagulation technique is used, minimal (if any) tissue can be sent. It is best that all pigmented lesions be sent for histology because this is a very litigious area of medicine, and the less "artifact" on a specimen the better.

The Ellman unit does have a "fulguration port." This setting provides a very intense but superficial burn/coagulation. It can be used in place of the coagulation mode in many instances, but in general it has little benefit over the coagulation setting and is rarely used.

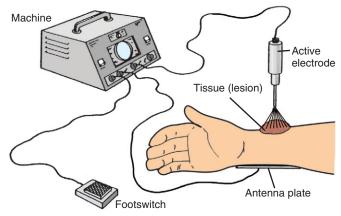

Novices are most concerned about the proper choice of settings when beginning electrosurgery. Here are some pointers:

- For removal of tissue, use pure cutting mode.
- For cutting the skin, or for the shave technique noted previously, usually an intensity of 2 (≤20 W) is sufficient. For removing large areas (e.g., cervical conization) or if the skin is hyperkeratotic, the intensity will need to be increased, but rarely over 4 (40 W) for the skin and 6 for the cervix. *Remember the "default" setting*: cutting, level 2. The larger and drier the tissue, the higher the power will need to be.
- When tissue destruction (matrixectomy, epilation, telangiectases) or bleeding control is needed, turn to the coagulation mode. Most applications will require a level of 3 (30 W). When small

**Figure 30-5** "Feathering" technique for lesion removal. Rather than removing the entire lesion in one pass, it is removed a small amount at a time. This avoids removing too much and going too deep, causing scarring.

- areas are treated without anesthesia (epilation, telangiectases of the face), reduce the power level to 1.
- Use the cut/coagulation mode when bleeding is likely (e.g., inner lip, buccal mucosa) or where scarring is not so much of an issue (external hemorrhoidal tags). The setting will need to be a little higher (3, or 30 W).
- For removal of cervical tissue, the goal is to limit tissue artifact
  so the pathologist can readily read the specimen and discern if
  the entire lesion was removed. Use a pure cutting mode; although
  scarring is not a concern, bleeding still is. Amazingly, however,
  there is generally very little bleeding, even with pure cutting, and
  the pathologist will be able to read to the margins of the excision
  because the cutting mode leaves little burn artifact. (See Chapter
  149, Loop Electrosurgical Excision Procedure for Treating Cervical Intraepithelial Neoplasia.)
- All electrosurgery will be accomplished easier at lower power (therefore causing less tissue destruction) if the tissue is moist and

**Figure 30-6** Diagrammatic illustration of radiosurgery showing the distribution of energy and the appropriate placement of the antenna plate near the lesion. (Courtesy of Ellman International, Inc., Hewlett, NY.)

TABLE 30-1 Proper Electrode Tips and Power Settings					
Procedure	Mode	Power (Ellman/Watts)	Electrode		
Condylomata	Cutting	2/20	Large or small round loop		
Ear piercing	Cutting or cut/coag	2/20	Narrow, pointed tip		
Electrodesiccation and curettage	Coag	3/25–30	Ball		
Epilation	Coag	1/10	Vari-tip, 33-gauge needle on hub adaptors, or insulated needle		
Epistaxis	Coag	3/30	Ball electrode		
Hemorrhoid tags	Cut/coag	3/25–30	Large loop or vari-tip		
Hemostasis, skin	Coag	2–3/20–30	Ball electrode		
Incisions	Cutting	2-3/20-30	Vari-tip, fine needle, blade		
LEEP	Cutting	4/35–40	Long, special LEEP electrodes		
LEEP	Coag base/hemostasis	6/40–60	Long, special LEEP ball		
Matrixectomy	Coag	2–3/20–30	Special insulated matrixectomy electrodes, raise up on the eponychium, do not overcoagulate		
Rhinophyma	Cutting	2/20	Large loop or rounded surgical blade (no. 10A)		
Shave excision/smoothing	Cutting	2/20	Large or small loop

Xanthelasma	Cutting	2/20–25	Large loop		

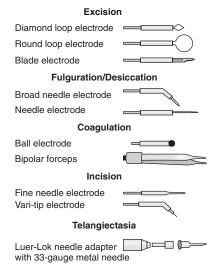

LEEP, loop electrosurgical excision procedure.

hyperkeratotic material has been removed. Use a moistened  $4 \times 4$  gauze pad and wipe it across the tissue after each pass or two.

- Most lesions will have to be anesthetized before removal with the RF unit
- In general, place the antenna plate or grounding pad as close to the lesion as possible to limit the spread of the current and increase the intensity at the desired site (Fig. 30-6).
- The proper electrode tips and power settings are summarized in Table 30-1.
- Be sure to hold the handpiece like a pencil, and place the fifth finger
  on the patient for stabilization. If the patient jumps or moves,
  your hand thus moves with him or her. Otherwise, the patient
  may experience a significant laceration or burn.

# **Specific Approaches for Various Lesions**

There are a multitude of applications possible with the variety of tips available (Fig. 30-7; see Fig. 30-1D). There are loop and straight-

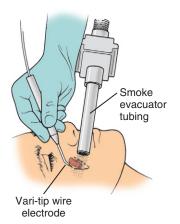

**Figure 30-7** Multiple electrode tips available for the Ellman Surgitron radiofrequency unit.

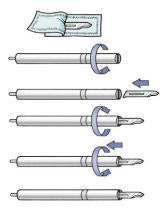

wire electrodes for excising, incising, or shaping tissue; ball electrodes for coagulation; and pointed rod electrodes for fulguration and desiccation. More specific electrodes are available for nail matrixectomies and LEEP of the cervix. The tips are changed in the handpiece much like the bits are changed in an ordinary drill. Most treatments are accomplished with simple local anesthesia, regional field blocks, or digital blocks. Radiosurgery is relatively atraumatic when correctly applied; consequently, the risks of scar tissue formation are minimal compared with those associated with scalpel surgery.

For the majority of cases, the handpiece is inserted into the color-coordinated "handpiece" port on the unit to enable the selection of various output modes. (If inserted into the "fulguration port," that will be the only output.)

Biopsies or excisions of lesions may be accomplished with the standard ellipse technique using the *vari-tip electrode* (Fig. 30-8) or a scalpel blade inserted into a *chuck adapter* (Fig. 30-9). The vari-tip has a fine wire that can be pulled out at variable distances to cut from 1 to 2 mm up to 1.5 cm deep. The unit is set at cutting mode. The proper power is usually between 2 and 3. The thickness and dryness of skin may cause some variation in the latter setting. Remove any hyperkeratinized tissue first, and be sure the skin is

**Figure 30-8** Use of the vari-tip wire electrode to carry out an elliptical excision.

**Figure 30-9** Technique of inserting scalpel blade into handle for radiofrequency surgery. Most surgery is carried out with the loop electrodes or varitip wire. The scalpel is used most frequently for "bloodless" undermining.

moist. In addition to incising and excising, these two electrodes are often used to undermine skin because bleeding will be controlled if the cut/coag (blend) mode is used. The cutting is very fast so be careful not to excise too deeply.

If the lesion to be removed is large and elevated, a biopsy specimen may be obtained by simply using the loop electrodes to remove the sample (Fig. 30-10). (See previously discussed precautions.) However, with smaller, flatter lesions, using the loop to obtain a shave biopsy specimen may cause sufficient artifact in the tissue specimen and obscure pathology. For smaller lesions, then, use a regular scalpel blade (without current) to obtain a shave biopsy specimen. Then use the loop electrode to smooth out the base and control bleeding. Remember, when obtaining a biopsy sample for suspected melanoma, the depth of lesion penetration is *very important*. Do *not* perform a shave biopsy of a pigmented lesion unless you are certain it is not a melanoma (see Chapter 32, Skin Biopsy).

Basal cell cancers are often best treated using a combination of curettement and cautery (or fulguration). A *ball electrode* is used in the handpiece with coagulation mode and the power set at approximately 3 to 4. After curetting the lesion, the base of the wound is cauterized. Cautery and curettement are usually carried out three times on the same visit. The tissue from the first curettement is sent for histology to confirm the clinical diagnosis (see Chapter 12, Approach to Various Skin Lesions, and Chapter 32, Skin Biopsy). Lesions less than 1 cm have a cure rate greater than 98%.

Condylomata acuminata may be excised using a loop electrode with the unit set at *cutting* (most commonly) or at *cut/coag* and power set at approximately 2 to 3. For larger lesions, "debulk" them with the initial pass, then successively remove more tissue, and finally feather out the edges with a very light touch. Be very careful not to go too deep and remove too much tissue with the first pass!

Using a colposcope for magnification during the removal is very helpful. (Alternatively, any residual after the initial pass may be removed with coagulation of the bases of the wound.) *Small warts* on all parts of the body may be destroyed easily using a ball electrode with the unit set at coagulation and a power setting just strong enough to "cook" the lesions (1 to 2). The smaller lesions can also be grasped with metal pickups and the electrode applied to the pickups while lifting the lesion. Apply enough current so that the lesion can be wiped off with moist gauze after coagulating it.

Xanthelasma may be treated easily using a large loop in the cutting mode set at level 2. Use very superficial passes over the lesion until all white material is removed. Use ophthalmic ointment to keep the wound moist until it is healed. No suture closure is required.

Fibroepithelial skin tags may be removed simply, usually without anesthesia, with the loop electrode on the cut (or cut/coag) mode and power setting at slightly less than 2 (Fig. 30-11). They can also be treated like small condylomata, as noted previously. Larger lesions will require anesthesia.

Hemorrhoidal tags can be removed similarly to skin tags. Be careful that the local anesthesia does not distort the base of the tag, which can create a false sense that more tissue has to be removed. This could leave a larger wound than needed. The cut/coag mode at level 3 to 4 works best. Usually the wound is left open.

Seborrheic keratoses are successfully treated using the technique described previously for shave excisions. Remember, the lesion is very superficial, so deep removal is not necessary. This will minimize scarring. Use a blade to shave off the bulk of the lesion and follow it with a large loop, cutting mode, and setting of 2, using the feathering technique.

Sebaceous cysts may be uncovered for intact removal or extraction of the capsule by using a small ellipse around the central pore. The cutting mode is selected and the power dial is set at no more than 2. The length and depth of the ellipse obviously depend on the size of the cyst and thickness of the skin. The vari-tip electrode is set at skin thickness (estimate). With an Allis clamp, put slight traction on the ellipsed area over the cyst wall itself. The lesion is then bluntly dissected from surrounding deep tissue and removed.

Telangiectases (face only) are effectively treated with the electrocoagulation technique. Use the coagulation (hemostasis) mode with the power set at 1, and a fine needle. A hypodermic needle adaptor is available for the handpiece; a short 33-gauge hypodermic needle with a metal hub is then attached to the adaptor for this procedure (see Fig. 30-7). Insulated needles can also be purchased from the manufacturer (Fig. 30-12). The special needles are insulated and active only at the very tip. Generally, topical anesthetic is used (see Chapter 10, Topical Anesthesia). Treatment lasts a fraction of a second. The unit is activated before touching the telangiectases. Vessels should be penetrated minimally at approximately 1- to 2-mm intervals. Begin distally and work proximally. (Doing the opposite—proximal to distal—causes the vessels to go into spasm, making them hard to locate.) Facial lesions respond the

Figure 30-10 Another technique for removing a raised skin lesion with a broad base. Care must be taken not to excise too much tissue.

Figure 30-11 Technique for removing a lesion with a pedunculated base.

Figure 30-12 Insulated needles available for treatment of telangiectasia. A, #D6-A, .004; B, #D6-B, .007; C, #D6-C, .009. (Courtesy of Ellman International, Inc., Hewlett, NY.)

best, whereas spider veins on the lower extremity do not resolve well. There is often prolonged pigmentation and recurrence with leg veins. Sclerotherapy is the procedure of choice for the lower extremities (see Chapter 92, Sclerotherapy). *Spider angiomas* anywhere can be treated with the fine needle. Occasionally all that is needed is coagulation of one central vessel. *Cherry hemangiomas* are best treated using light ball electrode desiccation, then wiped away.

**Epilation** of isolated hairs deploys a similar technique and needle. Choose the coag setting at level 1, grasp the hair with pickups, and slide the needle down the shaft. Activate the electrode; as the hair follicle is "cooked," the hair comes out easily. Trichiasis is treated in this fashion too. For large areas of unwanted hair, use the modern techniques of removal (see Chapter 48, Laser and Pulsed-Light Devices: Hair Removal).

Actinic keratoses are very dry and, unless small, are best treated with cryosurgery or shave technique. If the electrodesiccation technique is used, however, those lesions that do not respond appropriately should be studied further to rule out neoplastic changes. If there is any doubt, obtain a shave biopsy sample before treatment.

Plantar warts are treated in a multitude of ways (see Chapter 42, Wart [Verruca] Treatment). When other methods fail (e.g., Candida antigen injections, topicals, cryotherapy, bleomycin), the wart may have to be removed with curettement and coagulation. Perform this carefully because scarring on the bottom of the feet can cause painful nodules. Some residual scarring is the norm rather than the exception. After anesthesia, curette the lesion and follow with ball electrode coagulation. Curette again to ensure all wart tissue has been removed. Do not penetrate the dermis; warts are epithelial. Alternatively, a loop can be used to excise the lesion, but it frequently goes too deep (see precautions discussed previously). The electrified curette works very well, but it too can go too deep, too fast, and too easily. Be careful and go slow.

For ingrown toenail surgery, where ablation of part or all of the growth center is desired, the matrixectomy electrodes perform superbly (Fig. 30-13; see Chapter 29, Ingrown Toenails).

**Ear piercing:** Use the thin, pointed electrode at the cutting or cut/coag setting, 2 to 3, or 25 to 30 W. Identify the sites bilaterally and mark them. Stabilize the earlobe and then advance the tip through the anesthetized tissue. Remove the tip and insert the earring stud.

Cervical dysplasia: For those trained in colposcopy and treatment of cervical intraepithelial neoplasia (CIN), this unit can be adapted to the LLETZ (large loop excision of the transformation zone) procedure with a special set of electrodes designed for this

purpose (Fig. 30-14). This office procedure allows a "tailored" cervical conization (see Chapter 149, Loop Electrosurgical Excision Procedure for Treating Cervical Intraepithelial Neoplasia).

Rhinophyma: Extra tissue is removed using the large round electrode and sculpting the nose back to the original form (Fig. 30-15). Use pure cutting, level 2. Keep the tissue moist by continually wiping with a moist gauze pad.

Skin tightening (Radiage): The basic concept in skin tightening is to heat collagen, which then contracts during the healing process. No anesthesia is necessary. Special tips are used for this procedure (Fig. 30-16; see Chapter 52, Nonablative Radiowave Skin Tightening with the Ellman S5 Surgitron [The Pelleve Procedure]). The 10-mm "Radiage Wand" works for most areas, with the 5-mm one for areas around the eyes, where it is hard to maneuver.

For this procedure, the dual-frequency Ellman unit must be used. The cut/coag mode is preferred by some, although others use pure cutting, which also appears to create adequate heat. Long-term effects remain to be seen. Good immediate improvement can be seen in some patients, but contraction and, thus, tightening will continue for up to 3 months.

Typical power levels for the face are 16 to 20 W, with less for the neck (14 to 15 W) and much less for the eyelids (4 to 7 W) when done with the 5-mm tip.

Circular motions are recommended by the manufacturer, but a sweeping motion also works well. Most patients experience a pleasant sensation of warmth throughout the treatment of a given area until just before it is time to move the tip. At this point, it goes from feeling comfortable to very hot in a matter of 2 to 3 seconds. When the tip becomes too hot, move on to a new area. The excessive heat dissipates and patients are again comfortable in 2 to 3 seconds. Patients do not seem to mind this as long as the reason for it is explained to them at the beginning of the treatment.

Do not lift the wand off the skin with the handpiece activated. It will cause a small electrical shock that is uncomfortable for the patient.

Forty-five minutes is the typical treatment time for the face, including eyelids (use plastic eye shields). This does not include setup or cleanup time.

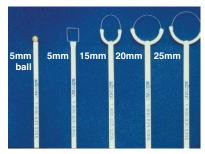

Ninety days is the expected time for revision and new collagen formation to be complete. Repeat treatment, if needed, may take place any time after that.

When using the eye shields, coat the inside with ointment-type eye lubricant to protect the corneal epithelium. Drops are not adequate. Erythromycin ophthalmic ointment works, but may cause

**Figure 30-13** Toenail matrixectomy electrodes. **A,** Wide blade, coated Teflon side up. **B,** Wide blade, brass uncoated side up. **C,** Narrow blade, coated Teflon side up. **D,** Narrow blade, brass uncoated side up. The brass (active) side goes down, facing the matrix. The Teflon (coated, protective side) faces and lifts up against the eponychium as it is slowly withdrawn. **E,** Proper application of the matrixectomy electrode into the nail groove.

**Figure 30-14** LLETZ (large loop excision of the transformation zone) electrodes used to perform office cervical conizations. (Courtesy of Ellman International, Inc., Hewlett, NY.)

allergic reactions. Consider "overnight" eye lubricants, such as GenTeal PM. Most of these seem to contain petrolatum (like LacriLube). The vision may be blurry for ½ hour or so after removal. This does not seem to be a problem if one treats the eyes first and then immediately removes the eye shields, giving time for the lubricant to dissipate during the remainder of the treatment (see Chapter 52, Nonablative Radiowave Skin Tightening with the Ellman S5 Surgitron [The Pelleve Procedure]).

Other lesions: These include tattoos, sebaceous hyperplasia, eccrine hidrocystomas, milia, verrucae plana, verrucae vulgaris, venous lakes, and trichoepitheliomas. For those performing laparoscopy, radiosurgical techniques can be used for endometriosis, pelvic inflammatory disease, myomectomy, and, in skilled hands, ectopic pregnancy. The vari-tip has also been used for

**Figure 30-16** Technique for skin tightening (Radiage) using the special handpiece and tip.

blepharoplasties. The larger, pointed tips can be used for body piercing. Uvuloplasties are quite simple using excision or ablation techniques.

**Warning:** As with laser, vaporization of viral particles (HPV and HIV) in the smoke plume that accompanies destruction or excision of tissues with these techniques has been documented. Those present in the room should wear protective masks, and a smoke evacuation system is mandatory (Fig. 30-17). The suction should be no further than 2 cm from the operative site. Proper vacuums have a viral filter as well as a charcoal filter to limit the offensive odor. Compact portable units are available from the same manufacturers who supply the ESUs.

Figure 30-15 Use of radiofrequency loop to treat rhinophyma. A, Preoperative appearance. B, Preoperative appearance of left naris. C, Using the loop to remove tissue after a nasal block with lidocaine. D, Immediate postoperative appearance. E, Two weeks postoperative appearance, right naris. F, Two weeks postoperative appearance, left naris. G, One month postoperative appearance.

**Figure 30-17** Smoke evacuator with both viral and charcoal filters. (Courtesy of Ellman International, Inc., Hewlett, NY.)

Some physicians have created their own vacuum exhaust systems leading to the exterior of the building or installed bathroom-type exhaust fans in the room.

Modern electrosurgery (RF) techniques are easily mastered and are best accomplished by attending a workshop on radiosurgery or by following the instructions given in Pollack's *Electrosurgery of the Skin*. These instructions can be practiced at home on a piece of beefsteak. Simplicity, economy, and versatility are unique to this instrument. The lesions that can be removed are myriad, depending on the practitioner's scope of practice and versatility.

# **Key Points**

- If the ESU is adjusted to the *correct settings*, the tissue will cut like soft butter.
- If the power is too low, the stroke too fast, the skin too dry, or the electrodes not totally clean, the electrode will stick or catch.
- If the power is *too high*, there will be excessive sparking and smoke. The principle is to *minimize* the lateral heat. Less tissue damage occurs with the finer the tip, the less energy used, the less time the electrode stays in one spot, the more moist the tissue, use of a cutting mode, and use of a higher-frequency unit:

$$H = \frac{T \times I \times W \times S \times R}{F}$$

where heat (H) depends on time (T), intensity of current (I), waveform (W), area of surface contact or electrode size (S), and resistance of tissue (R) divided by frequency (F).

 Once the lesion has been removed, any remaining bleeding can be controlled with topical astringents. Monsel's solution or aluminum chloride works best (see Chapter 40, Topical Hemostatic Agents).

# COMPLICATIONS

- Broken wire causing laceration (discard worn tips).
- Too deep an excision, causing excessive scarring and trauma to undesired tissue.
- Destruction of tissue for pathologic review, caused by improper technique.
- Handpiece in wrong port or unit in wrong mode to obtain desired effect.
- Pacemaker dysfunction.
- Inadvertent burns, on either the patient or operator, resulting from unintended activation of handpiece.
- Poor healing.
- Pain, bleeding, and infection (extremely rare).
- Scarring (usually very minimal, but could result in a depression, hypopigmentation, or hyperpigmentation).
- Incomplete removal of a lesion.
- Recurrence of the lesion.
- Inadvertent shaving of a pigmented lesion that turns out to be a melanoma.
- Spreading infection between patients.

- Explosion of colonic gas (methane) from exposure to a spark (if the patient is asleep, a moist gauze should be placed in the anus to reduce the chance of a burn if performing a procedure in that area).
- Sparks can cause explosions should alcohol or other flammable agents be nearby.

Although some of these complications can be avoided, they still do occur on occasion. Removing a lesion on someone who is on aspirin or anticoagulant therapy may be accompanied by increased bleeding, necessitating heavier use of the coagulation waveform. But do not discontinue warfarin, aspirin, or clopidogrel. Another complication that may be seen in diabetic patients or older patients with thin, poorly perfused skin is slow or delayed healing. In this case, patients can often be instructed in self-care of the wound, with periodic inspections by the physician. Performing any procedures with these techniques on the lower extremities of diabetic patients can certainly be fraught with problems related to healing delay and possibly secondary infection. Scarring must also be considered a complication; however, once proper technique is established, a scar by this method of treatment is often less pronounced than those produced by other surgical and excisional techniques. Excising too deeply increases the likelihood of scars.

#### POSTPROCEDURE PATIENT CARE

Several approaches are acceptable in the postprocedure care of these lesions. In general, the areas that were treated should be washed lightly four times per day with mild soap and water. The patient can use a washcloth for light débridement to prevent eschar formation. A topical antibiotic ointment is then applied as frequently as necessary to keep the lesion moist (even Vaseline will work). A dressing is not needed except at bedtime (or if under clothing) to ensure that the area stays moist (see the patient education handout online). Moist healing and prevention of eschar (scab) formation are essential to decrease the likelihood of scarring.

Moist healing can also occur when the lesion is simply covered with a small piece of synthetic material (e.g., Op-Site, Tegaderm) or the new Johnson & Johnson over-the-counter product called "Advanced Healing" (see Chapter 44, Wound Dressings). Leave these coverings in place for 1 week, provided there is not an excessive accumulation of serum. If serum does accumulate, the dressing should be changed. Usually, after 7 days, the wound can be left open to continue its healing process without any covering, unless it is in an area that may be irritated by clothing. This method is not practical in hair-bearing sites or if multiple lesions are removed.

# **CPT/BILLING CODES**

Billing codes for RF surgery are diverse depending on what was done. There is no special reimbursement if RF is used. Codes vary with the lesion size, benign or malignant characteristics, location, and type of removal. Some lesions would be billed out as true "excision." Others would be billed as "shave excision," and still others would be termed "destruction" or "biopsy." The reader is advised to consult the most recent CPT coding manuals and other sections of this text.

#### **ACKNOWLEDGMENT**

The author would like to thank J. Drlik, MD, for his contribution to the section on skin tightening (Radiage).

# RING REMOVAL FROM AN EDEMATOUS FINGER

John Harlan Haynes III • Andrew Thomas Haynes • Terrance S. Hines

Soft tissue swelling of a finger occurs with trauma, fluid retention, weight gain, arthritis, allergic reaction, infection, or iatrogenic infusion infiltration. When the finger is constricted by circumferential banding, such as with ring jewelry, venous outflow from the finger may be restricted, which can lead to nerve damage, ischemia, and digital gangrene if the ring is not removed promptly.

The involved finger should be evaluated initially for any lacerations or neurovascular compromise. This can be accomplished by testing for sensory deficits through the use of two-point discrimination to the distal fingertip and assessment of distal digital pulses with a Doppler flowmeter. In the absence of any signs of neurovascular compromise, ring-sparing techniques may be attempted initially; however, if signs of compromise are present, ring cutting is indicated. Embedded bands should be evaluated radiographically for bony involvement necessitating removal in the operating room.

Removal of a constricting ring is often described as a two-step process: (1) exsanguination of the finger and (2) removal of the ring. If a tourniquet is used to accomplish the first step, a maximum of 2 hours is recommended, although up to 4 hours has been reported. If ring removal is not accomplished by a trial of elevation, lubrication, application of ice for 5 minutes, application of a proximal blood pressure cuff, and circular traction, the clinician may use the various techniques for intact removal of a constricting band (e.g., string-wrap method or glove method). Alternatively, division of a constricting ring may be necessary using a variety of tools (e.g., conventional hand-operated or motorized circular saw, Steinmann pin cutter, wire or bolt cutters, or other commercially available cutting device). However, this damages jewelry and could injure the patient. Care should be taken to avoid implantation of metal filings, which may lead to foreign body granuloma and synovitis if the ring is cut. Rings removed by cutting are often repairable by a jeweler. After ring removal by any of these methods, a neurovascular examination should be performed as mentioned earlier. If any deficits in sensation or vascular flow are noted, prompt consultation with a hand specialist is required.

#### **INDICATIONS**

Acute or chronic finger edema with proximal band constriction

#### **RELATIVE CONTRAINDICATIONS**

- Open wound or fracture
- Deeply embedded ring erosion
- Lack of patient cooperation

#### STRING-WRAP METHOD

# **Equipment**

- Between 2 and 3 yards of string, braided suture of 0 gauge or larger, or umbilical tape—preferably on a spool
- Adhesive tape
- Small hemostat
- 1.5 mL of 1% lidocaine without epinephrine (optional)
- 5-mL syringe with 27-gauge needle for digital nerve block (optional)
- Lubricating K-Y Jelly, mineral oil, vegetable oil, or the like

#### **Technique**

- Some patients may require a digital block in case the pain increases from the compression and unwinding. If needed, 0.5 to 0.75 mL of 1% lidocaine is infiltrated deep into the neurovascular bundle on the proximal volar aspect of the affected finger bilaterally.
- 2. Lightly lubricate the finger near the ring. Pass the hemostat from distal to proximal under the ring, grasp the end of the string, and thread it beneath the ring, pulling several inches of string through (Fig. 31-1A). Tape the proximal end to the hand (Fig. 31-1B).
- 3. Wrap the string circumferentially around the finger, beginning just adjacent to the ring margin. Care should be taken to not wrap the string so tight as to obstruct arterial flow. Wind the string in a smooth single layer going distally, using moderate tension until it encompasses the point of greatest swelling (Fig. 31-1C).
- 4. Untape the proximal end of the string and pull distally toward the fingertip. Maintain tension along the long axis of the finger, moving the ring distally as the string unwinds beneath it. Force the ring over that portion of the finger that has been compressed by the wrap (Fig. 31-1D). Once past the area of largest diameter, usually the proximal interphalangeal joint, the ring will slide off easily.
- 5. Variations, including wrapping proximally to distally as well as vice versa, have been described. A number of devices have been used for this "sequential compression," including suture, thread, or floss; thicker umbilical tape, ribbon gauze, or tape; or more elastic items such as an intravenous tourniquet, rubber band, or Penrose drain.

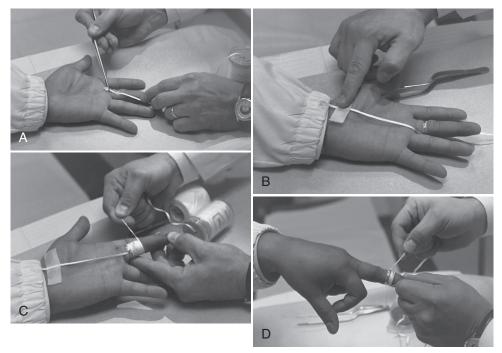

Figure 31-1 A-D, String-wrap method of removing ring from a swollen finger. See text for details.

# CIRCULAR SAW OR STEINMANN PIN CUTTER METHOD

# **Equipment**

- Hand-held circular-blade ring cutter (e.g., Beaver) or Steinmann pin cutter with a McDonald elevator
- Large hemostats (e.g., Kelly clamps)
- 20-mL syringe filled with saline and 20-gauge Intracath sheath

# **Technique**

- 1. Begin by draping the patient and providing eye protection to all persons in the work area. Slip the small hook of the ring cutter or elevator under the ring on the palmar surface to serve as a guide and barrier (Fig. 31-2). If elevation of this section is necessary for application of the ring cutter, the ring may be bent outward by using pliers with the jaws placed at 90 degrees from the cutting site.
- 2. Firmly grip the saw handle, and, using a 180-degree twisting motion, grind through the ring. Using the pin cutter, cut through the ring, over the elevator. This process generates heat and may be interrupted every 30 seconds to allow ring cooling to prevent further injury to the patient. Irrigation is helpful, but careful drying is necessary if electric tools are being used. Because sparks

Figure 31-2 Hook of the ring cutter serves as a guide and barrier.

- may be produced, flammable items (e.g., rubbing alcohol) must be removed.
- The cut ends of the ring may be spread using hemostats with steady opposing force. If the ring must be cut in two places, sharp edges should be protected with a gauze covering.
- Rinse the area with high-pressure saline to ensure evacuation of all metal filings.
- Alternatives include the Moody GEM II motorized ring cutter, Dremel MultiPro+ cutting tool, fire department extrication tools, and carbide dental drills.
- 6. In cases of titanium or tungsten alloy bands causing constriction, we recommend the use of a high-speed Dremel tool with an abrasive carbide cutting wheel. A variable-speed Dremel tool and one-inch carbide cutting wheel are available at most hardware supply stores. The medial and lateral sides of the finger must be supported with malleable ribbons and the finger should be protected by a stainless steel ring support under the ring. A bulb syringe with sterile water is used to keep the ring as cool as possible while cutting. It may be necessary to consult a team member from maintenance or plant operations who is experienced in using a Dremel tool.

# SURGICAL GLOVE METHOD

# **Discussion**

- Not universally recommended
- Can be used in the presence of fractures or soft tissue injury
- Causes minimal additional pain

# **Technique**

- 1. Cut one finger from a surgical glove (Fig. 31-3).
- 2. Place on involved finger.
- 3. Slip proximal end under ring using hemostats (Fig. 31-4A).
- 4. K-Y Jelly may be used to lubricate.
- 5. Pull proximal end back over ring (Fig. 31-4B).
- Continue to pull and twist on the retroverted glove to advance ring distally (Fig. 31-4C).

Figure 31-3 Materials needed for ring removal from an edematous finger using the surgical glove method: surgical glove, hemostat, scissors. One finger is cut from the glove and the tip is removed to form a "sleeve."

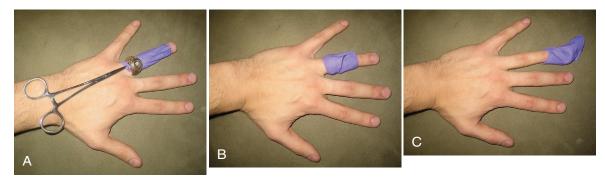

Figure 31-4 A, The rubber sleeve is pulled under the ring. B and C, The sleeve is pulled over the ring, removing it from the finger.

 A variant of this technique involves using a Penrose drain. In the event of a failed removal, the drain may act as insulation against electrical burns should electrocautery be required during surgery.

# POSTPROCEDURE PATIENT CARE

- Consider appropriate tetanus prophylaxis.
- Consider antibiotics in cases of contaminated wounds, patients with diabetes, patients with comorbidities, or the immunocompromised.

# **CPT/BILLING CODES**

Ring removal is considered part of the standard evaluation and management (E&M) otherwise provided to the patient. However, if the ring removal were provided in the setting of a finger fracture, an appropriate CPT code (open, closed, manipulated) may be used if definitive treatment is provided. If definitive treatment is referred to another physician, coding for supplies and splinting may be used.

O There is no specific code for removal of a ring. Use the appropriate E&M code.

# SKIN BIOPSY

John L. Pfenninger

Examination and appropriate history suffice to establish most dermatologic diagnoses. At times, however, biopsies are necessary. A skin biopsy is typically performed to make or confirm a diagnosis and to guide definitive treatment. In many instances, a biopsy serves as the means of both diagnosis and treatment if it removes the entire lesion. Needle aspiration biopsy (see Chapter 226, Fine-Needle Aspiration Cytology and Biopsy) is usually reserved for deeper lesions but at times can also be used to diagnose skin lesions.

Skin biopsies are generally quick, simple, and cost effective. Diagnoses obtained by biopsy also serve to build a physician's experience and skill in dermatologic diagnosis by providing feedback and confirming the clinical diagnosis, perhaps reducing the need for future biopsies of similar lesions.

To enable the pathologist to provide the most information possible, provide a good history with each specimen submitted. Include aspects of the "seven Ds":

- 1. Demographics (e.g., patient's age, history of travel, location of lesion)
- 2. Diseases (other diseases the patient has [e.g., lupus])
- 3. Duration (how long it has been present)
- Drugs applied to the lesion or taken by the patient that could be the cause or change the appearance of the lesion (e.g., topical or oral steroids)
- 5. Description (e.g., papular, vesicular, hyperkeratotic)
- 6. Diameter
- 7. Diagnosis suspected

Skin biopsies are either partial or full thickness. Partial-thickness biopsies include shave excision and curettage. Full-thickness biopsies include standard excisional and incisional biopsies and the punch biopsy. Punch biopsies take only 5 to 7 minutes to complete; excisional or incisional types take longer. All of these may readily be incorporated in a primary care setting and can be performed when the patient first presents.

Priorities to be kept in mind when performing skin biopsies are (1) maintaining patient comfort and safety, (2) obtaining an appropriate tissue sample for pathologic diagnosis, and (3) producing the best cosmetic (least scarring) and functional result possible. Although written consent forms are usually not necessary for a skin biopsy, it is still important that patients understand the nature of the procedure, why it is being performed, and the possible complications.

# **INDICATIONS**

- To obtain a tissue sample for diagnosis by histopathology, electron microscopy, or immunofluorescence testing
- To perform an excision for curative or cosmetic purposes
- To obtain a deep culture (bacterial or fungal) while avoiding superficial contamination of wounds (e.g., decubitus ulcers)

**NOTE:** Lyme disease can be confirmed through cultures of biopsy material.

In general, the main reasons to do a skin biopsy are to rule out cancer and to determine the disease process present. If the physician's answer to the question "What is it?" is "I don't know," that may be an indication for biopsy (not necessarily referral). The next question should be, "Could this be a melanoma?" If the answer is "yes," then a full-thickness biopsy (punch, incision, or excision) is indicated.

#### **CONTRAINDICATIONS**

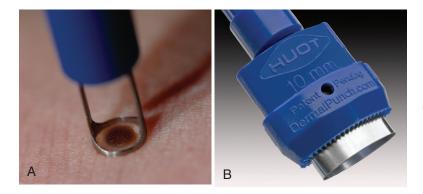

- Significant coagulopathy (warfarin, clopidogrel, and aspirin do not need to be stopped).
- Preparations, anesthetics, preservatives, or other materials to which the patient is allergic.
- Partial-thickness biopsies are discouraged if not contraindicated if melanoma is suspected (must "biopsy for depth").

A biopsy does not spread or activate the disease, distort a future diagnosis of a melanoma, or compromise future care (unless possibly if a melanoma is shaved and transected). The only potential error that can be made in sampling a lesion is to shave a melanoma and not include the entire depth. If the entire lesion is removed so its depth can be assessed, there is no consequence. However, if when performing a shave biopsy/removal, part of the lesion is left behind, thereby making it impossible to determine prebiopsy thickness, it could compromise appropriate care. Melanoma treatment and prognosis are based on depth of the neoplasm. Thus, if there is a true consideration for melanoma, it is best to perform "biopsy for depth," which means a punch or excision. The fear that any pigmented lesion "could be" a melanoma should not deter a clinician from doing a biopsy. In practice, the majority of atypical nevi are removed using a shave technique. It is impractical to remove every such nevus with a full-thickness frank excision using suture closure. It is far better to shave and transect a melanoma than to ignore a lesion and miss the melanoma. The point is to sample suspect lesions, or to refer the patient for biopsy and definitive care.

# **EQUIPMENT**

- Nonsterile gloves (sterile if sutures are to be placed)
- Alcohol wipes
- Local anesthetic (0.5 to 1.0 mL of 1% to 2% lidocaine with or without epinephrine)
- Hemostatic agents (see Chapter 40, Topical Hemostatic Agents)
- Antibiotic ointment
- Adhesive bandage
- Specimen container, usually containing formalin

**NOTE:** Tissue for culture may need to be placed in saline, whereas immunofluorescent studies may require that the tissue be placed in dry ice. Check with the pathologist to determine the proper handling of tissue for the diagnosis of Lyme disease.

**Figure 32-1** Biopsy punch tools. **A**, The VisiPunch. **B,** The Elliptiscalpel. (Courtesy of Huot Instruments, Menomonee Falls, Wisc.)

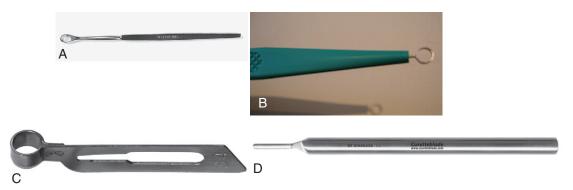

Figure 32-2 A, Fox dermal curette (reusable). B, Disposable curette. C, Disposable curette blade. D, Curette blade with smooth handle.

# For Punch Biopsy

- A 2-, 3-, or 4-mm punch biopsy tool; disposable biopsy punches are convenient and inexpensive, and it is not necessary to clean, sterilize, or sharpen them. The 2-mm punch is used only for areas where scarring is to be avoided because such a small amount of tissue may lead to a missed diagnosis, or the tissue can become inappropriately crushed. Biopsies over 4 mm in size will leave more scarring and, if sutured, may leave a "dog-ear effect." Newer disposable punches (VisiPunch, Huot Instruments, Menomonee Falls, Wisc; Fig. 32-1A) allow better visualization of the tissue being sampled, whereas other types (the Elliptiscalpel, Huot Instruments; Fig. 32-1B) can remove larger lesions by performing an elliptical excision.
- Pickups.
- Sharp fine tissue scissors.
- Suture kit or Steri-Strips (only if the biopsy site is 4 mm or larger).

# For Curettage

A dermal curette (Fig. 32-2) is used. *Disposable* curettes are recommended for nonmalignant lesions. Disposables are very sharp and will cut into the skin quite readily so must be used with caution. They do have a tendency to bend if a lesion is fibrotic (e.g., verruca). *Reusable* curettes do not bend but are not as sharp and often are inadequate for benign lesions where tissue adhesion is good. Neoplastic tissue (e.g., basal cell carcinomas, squamous cell carcinomas), on the other hand, is necrotic and easily curetted. When used for this purpose, reusable curettes are also less likely to cut into the normal skin structures. The curette blade (see Fig. 32-2C and D) is interesting and has some excellent features. The curette is disposable, so it is sharp and fits on a scalpel handle. It also does not bend, so when curetting fibrotic tissue, like verrucae, it maintains its shape

Figure 32-3 No. 10, 15, and 11 scalpel blades used for shave excisions.

and curetting function. Curettes of 2, 3, 4, 5, and 6 mm should be available. The size used depends on the size of the lesion.

# For Shave Excisions

A single-edge flexible razor blade or scalpel blade (no. 10 or 15) is used (Fig. 32-3). A scalpel handle is not needed; not only does it take time to insert and remove the blade on the handle, but medical personnel can be injured during the process. The blade itself or a radiofrequency unit may be used to smooth out the surface after the shave excision. (See Chapter 30, Radiofrequency Surgery [Modern Electrosurgery], to review the technique.) Sharp tissue scissors (Metzenbaum) can also be used to perform the "shave" by clipping off elevated lesions.

TABLE 32-1 Selection of Biopsy Site Based on Lesion Type				
Lesion Suspected	Where to Biopsy			
Basal cell carcinoma Squamous cell carcinoma Melanoma Vesiculobullous disease Rashes	Raised, nonulcerated area Central, thickened area Darkest, raised portion Fresh lesion at the margin; include some normal tissue (see Fig. 32-4) Primary lesion without secondary excoriation or infection			

Normal tissue is not needed in most instances (only with vesiculobullous lesions). A biopsy does not spread cancer.

In sampling a suspected melanoma, go for depth (i.e., a punch instead of a shave). Most chronic dermatitis is nonspecific on biopsy. A dermatologic consult may be indicated and be more beneficial.

#### For Incisions and Excisions

- Minor surgical or laceration tray with scalpel, skin hooks, pickups, tissue scissors, and suture (see Chapter 21, Incisions: Planning the Direction of the Incision; Chapter 22, Laceration and Incision Repair; and Chapter 24, Laceration and Incision Repair: Suture Selection)
- Radiofrequency unit if desired (see Chapter 30, Radiofrequency Surgery [Modern Electrosurgery])

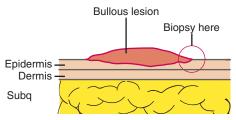

# **TECHNIQUE**

# Choosing a Biopsy Site

Although any skin area can be sampled, being selective improves final outcome. See Table 32-1 for recommendations specific to particular lesions and Table 32-2 for anatomic sites.

It is *not necessary to include normal tissue* in the sample, except when sampling a vesiculobullous lesion. It is then necessary to sample (usually a punch) right at the margin where the epidermis is being lifted from the underlying tissue (Fig. 32-4). If the lesion is small, a deep shave removing the entire lesion is also acceptable.

TABLE 32-	2 Site-Specific Biopsy Guidelines
Location	Comments
Breast	Punch or shave
Cervix	Mini-Townsend or baby Tischler forceps (see Chapter 137, Colposcopic Examination)
Eyelid	Sharp tissue scissors for shave removal
Gingiva	Shave; consider radiofrequency unit to limit bleeding if lesion is elevated
Intra-anal	Cervical biopsy forceps or flexible sigmoidoscopy biopsy forceps
Lip	Punch (bloody; heals quickly) or shave
Muscle	See Chapter 228, Muscle Biopsy
Nail bed	Remove portion of nail; use small punch (see Chapter 27, Nail Bed Repair)
Penis	Thin skin; use shave technique; stay superficial; scissors or sharp curette works best
Perianal	Sharp tissue scissors
Pinna	Shave; superficial punch; curette
Tongue	Punch; bloody; use suture; curette
Trunk	Any method
Vagina	Cervical biopsy forceps
Vulva	Hair-bearing area: use punch for depth Non-hair-bearing area: shave biopsy (see Chapter 159, Vulvar Biopsy)

**Figure 32-4** Obtaining a skin biopsy when a vesicle or bulla is present. Normal tissue should be included in the specimen. "Fresh" lesions that have not ruptured and are not crusted should be chosen.

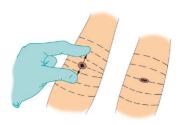

When there are multiple lesions that could be sampled, avoid the following areas:

- Cosmetically important areas
- Upper chest and deltoid regions, where hypertrophic scarring is more common
- Fingers, toes, and areas overlying joints
- Regions in which secondary infection (e.g., axillae and groin) or delayed healing (e.g., pretibial) is common
- Areas that compromise underlying structures, including superficial nerves and vessels
- Old lesions (choose well-developed but "fresh" lesions free of excoriation or excessive inflammation)
- Ulcerated lesions (if the only available lesion is ulcerated, include a border of the lesion in the specimen)
- Areas of poor circulation

# **Punch Biopsy**

The punch biopsy instrument is used to obtain a full-thickness cylindrical specimen. Punch biopsy is a good choice for complete removal of small lesions (<5 mm) or whenever there is doubt as to the diagnosis or optimal treatment for a particular lesion. It is strongly recommended when melanoma is a significant consideration because it provides information on the depth of the lesion. The whole lesion does not have to be removed at the time of biopsy, and a biopsy does not change the natural history of the lesion's progression in any way.

- 1. Prepare the selected site with alcohol. Sterile technique should be followed if sutures are intended; otherwise, nonsterile gloves can be used. Biopsies of 2 or 3 mm do not need to be closed with sutures. A 4-mm biopsy on the face may need to be sutured, and a 5-mm biopsy nearly always requires suturing.
- 2. Place a ring of anesthesia around the lesion (field block) or deep to the lesion.
- 3. Choose the appropriate-sized punch unit (2 to 5 mm). Remember that 2-mm biopsies may not provide adequate tissue for diagnosis and are somewhat difficult to handle. To minimize scarring, stretch the skin on both sides of the planned biopsy site away from the site, perpendicular to the lines of minimal skin tension, using the thumb and index finger of the nondominant hand (Fig. 32-5). Then push the unit vertically into the skin and rotate it back and forth to cut through the skin to the subcutaneous fat (Fig. 32-6A). A decrease in resistance should be felt at the point where the dermis is completely penetrated (much like doing a lumbar puncture).
- 4. Withdraw the punch. Push down with the fingers on each side of the biopsy. If the "plug" goes down with the skin, the biopsy has not gone deep enough. If the plug pops up instead of going down, then the adipose tissue has been entered and the tissue has been freed adequately. Gently grasp the specimen with forceps or a skin hook. Lift the specimen and free it by cutting the subcutaneous base with sharp tissue scissors (Fig. 32-6B and

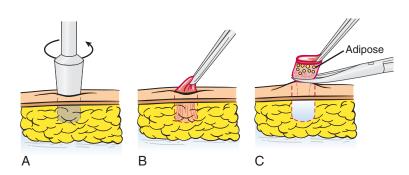

**Figure 32-5** Proper stretching of skin tension lines before punch biopsy (arm). On release, the tendency of the skin is to make the circular biopsy become more elliptical and thus more cosmetically pleasing when healed.

- C; Fig. 32-7). Apply pressure for hemostasis. Avoid chemical astringents in punch sites if the wound is to be closed with sutures, Steri-Strips, or glues; otherwise, apply Monsel's solution, aluminum chloride, or Gelfoam to control the bleeding. (Biopsies 3 mm or less rarely, if ever, need closure.) Rarely, electrocautery will be needed to control bleeds. A small pressure dressing with a folded 2 × 2 gauze under a Band-Aid is usually sufficient (Fig. 32-8).
- 5. Large punch instruments (>5 mm) are available, but closure of these wounds may require conversion of the circular defect into an ellipse because closure would otherwise cause "dog ears." Alternatively, consider using the Elliptiscalpel.
- 6. Use of absorbable sutures provides the same outcome cosmetically as does the use of nonabsorbable sutures, but they are more costly. With punch biopsies of 4 mm or less, outcomes are the same regardless of whether a suture is placed.

# Curettage

Curettage is a partial-thickness technique and is particularly well suited for biopsy removal of basal cell carcinomas and hyperkeratotic epidermal lesions such as warts, molluscum contagiosum, seborrheic keratoses, and actinic keratoses (see Chapter 12, Approach to Various Skin Lesions). A potential disadvantage of curettage in terms of obtaining a laboratory specimen is that, usually, multiple fragments of specimen are produced and the presence of disease-free margins cannot be determined. The physician performing the procedure decides if the removal is adequate. Many times, the initial curettement will reveal necrotic tissue consistent with a neoplasm such as a basal cell carcinoma. If it is elected to proceed with treatment at that time, only the first curettement specimen is sent to pathology.

**NOTE:** With benign lesions, it is clinically apparent when the abnormal tissue has been removed. For treatment (not just biopsy) of malignant lesions, continue curettement until there is a "gritty" tissue sensation, which is then followed by cautery. This process of curettement followed by cautery is done three times to ensure complete removal of any foci of *neoplastic* tissue (e.g., basal cell carcinoma, advanced actinic keratosis, or squamous cell carcinoma).

Prepare the area with alcohol and obtain an anesthetic wheal.
 Use the curette to scrape away or scoop out the lesion, typically
 in multiple fragments. Send the curetted tissue to pathology.
 (Remember to use disposable instruments for more fibrotic
 lesions and reusable curettes for necrotic tissue; see earlier
 discussion.)

- 2. Continue the curettage until only normal tissue remains at the margins. Usually, this is the upper aspect of the dermis, which feels "gritty" or "sandy" under the curette and demonstrates punctate surface bleeding. Use hemostasis as needed with topical hemostatic agents or light ball cautery. Carcinomas and severely dysplastic lesions generally feel soft and scrape out easily. Remember, when using curettage to treat a carcinoma, repeat a process of curettage and cautery three times (Fig. 32-9; see Chapter 12, Approach to Various Skin Lesions).
- 3. If, in the case of cancer, curettage (or shave excision) produces a full-thickness skin wound and adipose tissue is entered, this indicates that the tumor has probably invaded below the dermis. Set up a sterile field, excise the area, and close the wound with suture.

# **Shave Biopsy**

Shave biopsy is used frequently and is best suited to remove the protruding portion of a raised skin lesion when a full-thickness sample is not required. Flat lesions such as nevi also can be removed/sampled using this technique, but rather than shaving flat across the surface, a saucer-shaped incision is made to go deeper in the center to remove the lesion.

Shave excisions should not be performed if a melanoma is suspected because they may interfere with the pathologist's ability to grade the depth of invasion. A melanoma is treated based on the depth of invasion, and a difference of 0.1 mm or even 0.01 mm could be the difference between little further treatment and a radical resection. Lesions most amenable to shave excision include compound or intradermal nevi, skin tags, seborrheic keratoses, actinic keratoses, lentigines, and small basal cell carcinomas.

Advantages of shave excision include minimal time requirement, simple equipment, lack of need for suturing, and generally excellent cosmetic results. Also, the pathologist can determine if the entire lesion has been removed.

- 1. Prepare the area with alcohol and use clean technique; sterile gloves are not necessary. Reserve full sterile setup for full-thickness skin excisions that will be sutured. Instill a local anesthetic within the dermis underneath the lesion to elevate the lesion slightly, facilitating removal.
- 2. Excise the lesion by shaving with a slightly bowed, flexible, single-edge razor blade or with a scalpel blade kept parallel to the skin (Fig. 32-10). The resulting defect should be essentially level,

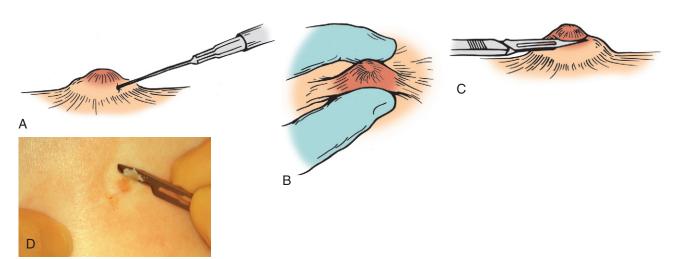

Figure 32-10 One technique of shave biopsy. **A,** Inject a local anesthetic to elevate the lesion. **B,** Roll the skin between the thumb and forefinger to create a flat cutting surface and a tamponade effect on the surrounding blood vessels. **C,** Holding a no. 15 blade parallel to the skin or at a slight downward angle, shave the lesion flush with or slightly below the surrounding skin. **D,** Shave technique using a no. 15 blade. No scalpel handle is necessary. (**A–C,** Courtesy of The Medical Procedures Center, PC, Midland, Mich.)

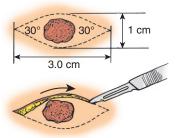

Figure 32-11 Elliptical excision biopsy technique. See text for details.

or minimally depressed, in relation to the surrounding skin. The greater the depth of the shave into the dermis, the more likely there will be resultant scarring. Apply simple pressure, pinpoint electrodesiccation, radiofrequency loop smoothing (pure cutting level 2/20 watts), or topical agents such as aluminum chloride or Monsel's solution to achieve hemostasis. Topical applications theoretically may inhibit healing. Monsel's solution and silver nitrate carry the risk of temporary staining.

- 3. Shave excision can also be performed using a radiofrequency loop. Heat artifact may occur at the margins of the excision, hindering histopathologic evaluation, or in the case of a very thin lesion, obliterating the lesion entirely. Also, because of the ease of cutting with the radiofrequency unit, the novice user may inadvertently go too deep with the loop, causing excessive and unnecessary scarring. Many practitioners perform a shave biopsy with a scalpel blade then use a radiofrequency loop to "feather out" the edges of the defect created to complete the procedure (see Chapter 30, Radiofrequency Surgery [Modern Electrosurgery]).
- 4. Sharp tissue scissors can be used, especially for pedunculated lesions, to effectively shave off the abnormality.
- 5. A variation of the shave biopsy is the **saucer excision.** With this technique, the central aspect of the biopsy, instead of being flat, is more depressed than the periphery. This technique might be used for actinic lesions, nevi, or dermatofibromas. In cases of suspected dysplastic nevi (but not a melanoma), one may cautiously perform a "deep saucer shave" because it allows histopathologic review of the tissue to ensure everything has been removed. Be sure, however, not to partially transect a melanoma; this is a very fine line. When in doubt, perform a deep punch biopsy first to confirm the nature of the lesion.

# **Excisional or Incisional Biopsy**

An excisional biopsy is used to remove an entire lesion in a manner that obtains a full-thickness specimen of skin. It generally refers to traditional frank excision with suture closure. Diagnosis and treatment can be carried out at the same time. Excisional biopsy can be used for removal of malignant, or suspected malignant, skin lesions where margins can be assessed. The problem with this approach is that the recommendations for "clear margins" vary depending on

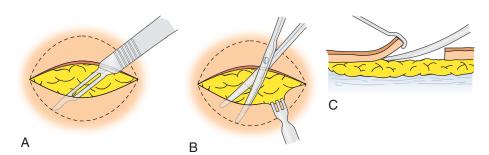

the lesion involved (e.g., 1 to 2 mm for benign lesions, 3 mm for a basal cell carcinoma, 5 mm for a squamous cell carcinoma, 10 mm for invasive melanoma <1 mm deep), and this is often unknown until the histology report is obtained. Doing a primary excision for a biopsy may lead to an excessive and unnecessarily large excision, or may require repeat surgery so that more tissue can be removed. An **incisional biopsy** removes only a portion of a larger lesion, and residual abnormal tissue remains. In general, a single punch biopsy (or more, if the lesion is very large) would be quicker and more acceptable when the diagnosis is uncertain. Then, once the diagnosis is known, appropriate treatment may be addressed.

- 1. In performing an excision, use sterile technique. Establish anesthesia, preferably in a field block pattern. Use a surgical marking pen to outline the planned margins of excision, and orient the long axis of the excision parallel to the lines of minimal skin tension (see Chapters 22, Laceration and Incision Repair, through Chapter 25, Laceration and Incision Repair: Suture Tying). Form the planned excision in the shape of an ellipse with a length that measures three times its width. The corners of the ellipse should subtend approximately 30 degrees (Fig. 32-11). See Chapter 12, Approach to Various Skin Lesions, for a discussion of appropriate margins for various lesions.
- 2. With the scalpel, make the initial incision along the outlined excision, then free up one corner of the ellipse, excising the full thickness of skin. Excise from one end to the center, then from the opposite end to the center, obtaining a specimen of uniform thickness. (A common error is to perform only a partial-thickness excision in the corners or lateral aspects of the wound.)
- 3. After the specimen is freed, undermine the edges on each side of the wound to a distance measuring the width of the original wound (Fig. 32-12). Undermine between the dermis and subcutaneous tissue with a scalpel blade, tissue scissors, or a radiofrequency unit using a vari-tip or fine needle with the unit set on the cut and coagulation setting.
- 4. A simple single-layer closure suffices for wounds with minimal tension. Otherwise, absorbable subcutaneous sutures (e.g., Dexon, Vicryl, PDS II) placed with an inverted knot can be used to reduce tension on the skin edges before final closure is completed (Fig. 32-13; see also Chapter 22, Laceration and Incision Repair).

NOTE: The following topics can be found in their respective chapters: planning the excisional site (Chapter 22, Laceration and Incision Repair), choosing and administering the anesthetic (Chapter 4, Local Anesthesia), selecting the suture (Chapter 24, Laceration and Incision Repair: Suture Selection), performing proper closures (Chapter 25, Laceration and Incision Repair: Suture Tying), and choosing dressings (Chapter 44, Wound Dressing).

# **COMPLICATIONS**

- Pain: Generally insignificant.
- Infection: If the patient washes the area three to four times per day with soap and water and applies ointment (antibiotic or otherwise) to keep it moist, there is rarely an infection.

**Figure 32-12** Subcutaneous undermining to release tension on wound margins with scalpel (**A**) and scissors (**B**). Proper level for undermining within subcutaneous fat (**C**).

Figure 32-13 Deep inverted absorbable sutures to close dead space after excision.

- Excessive bleeding: Almost nonexistent.
- Scarring: Always a possibility. With punch biopsies, there may
  be an "acne-like" pockmark. Obviously, excision and incision
  leave a line and possibly suture tracks. All methods can leave
  hypopigmentation. Some topical hemostatic agents (Monsel's
  solution and especially silver nitrate) can leave prolonged
  hyperpigmentation.
- Missing the correct diagnosis: A lesion may be sent for biopsy, but unless it is totally removed, the most significant area could be missed. (Likewise, the practitioner could unknowingly shave and transect through a melanoma; therefore, if there is any doubt, perform the biopsy for depth.)
- Allergic reactions: To topical antibiotics, the anesthetic, dressings, and other agents (usually indicated by redness and itching).
- Recurrence: Even if it was thought that the entire lesion was removed, both benign and malignant lesions can recur.

#### POSTPROCEDURE PATIENT EDUCATION

Shave excisions and curettage require moist healing, as described for radiofrequency shave excisions in Chapter 30, Radiofrequency Surgery (Modern Electrosurgery). Care for sutured full-thickness wounds is like that for primary clean lacerations and incisions described in Chapter 22, Laceration and Incision Repair.

# SKIN GRAFTING

Thomas N. Told

# PINCH (PATCH) GRAFTING

Pinch grafting (also known as patch grafting; first described in 1872) is a method of treating leg ulcers by grafting small pieces of full-thickness skin, usually harvested from the patient's medial thigh, to the ulcer site. With pinch grafting, leg ulcer healing rates of 20% to 50% can be anticipated, depending on the cause of the ulcer. Pinch grafting should be considered as an adjunct to conservative therapy and a therapeutic alternative for the inpatient or ambulatory management of leg ulcers. (Chapter 41, Unna Paste Boot: Treatment of Venous Stasis Ulcers and Other Disorders, describes another method for treating lower extremity venous ulcers using the Unna boot.) Pinch grafting requires no special training and no specialized equipment or supplies, but it does require a prolonged period of leg elevation and bed rest after the procedure.

#### **Indications**

Pinch grafting can be used to treat any *leg ulcer* or any other small, slow-healing ulcer of the trunk or extremities. Success rates for pinch grafting are highest for arterial ulcers (50%) and lowest for venous ulcers (20% to 40%). Compared with patients treated with conservative therapy, patients treated with pinch grafting have a shorter time to healing (reepithelialization) and a longer time until ulcer recurrence.

# **Contraindications**

- Allergy to anesthetic or antiseptic agents
- Skin infection at potential donor sites
- Lack of granulation base in ulcer (relative contraindication)
- Patient unwillingness or inability to comply with postprocedure instructions

#### **Equipment**

- Syringe and needle for anesthetic injection
- 1% or 2% lidocaine without epinephrine
- Antiseptic agent for donor site preparation (e.g., povidoneiodine)
- Sterile drape for donor site
- Sterile gloves
- Tissue forceps with teeth
- Scalpel with no. 15 blade
- Ruler
- Dressings for grafted ulcer (options include petrolatum [Vaseline]
  impregnated gauze; saline-soaked fine-mesh gauze; Adaptic
  [Johnson & Johnson, New Brunswick, NJ] nonadhering dressing;
  Xeroform gauze [Kendall, Mansfield, Mass]; or Biobrane [Smith & Nephew, Hull, United Kingdom])
- Two layers of dry gauze and a light pressure dressing
- Telfa pad (Kendall) to transport grafts

Vaseline gauze, Telfa pad, or Adaptic or Xeroform gauze for dressing the donor site (there is also a dissolving Vaseline gauze that works well)

# **Preprocedure Patient Preparation**

The patient must be willing and able to comply with postprocedure activity restrictions. The leg ulcer(s) must be clean and must have a granulation base. The ulcer base can be débrided with wet-to-dry saline gauze dressings for 3 to 4 days before the procedure. The relative risks and benefits of pinch grafting should be explained to the patient. All supplies and equipment should be gathered at bedside or in the examination—treatment room. The ulcers should be measured to provide an estimate of the number of grafts needed. The donor site (the proximal medial thigh is preferred) and the skin around the ulcer(s) should be prepared in a sterile manner. Pinch grafting should be performed under sterile conditions.

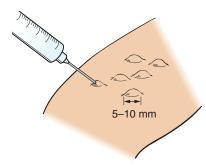

# **Technique**

- 1. Prepare and drape both donor sites and ulcer(s).
- 2. Measure the ulcer(s).
- 3. *Inject local anesthetic* (without epinephrine) into the donor site to form wheals of 5 to 10 mm in diameter (the number of wheals should equal the number of grafts needed; Fig. 33-1).
- 4. Grasp the anesthetized skin with the tissue forceps and *remove* full-thickness skin pieces 3 to 5 mm in diameter, avoiding subcutaneous fat (Fig. 33-2). Trim off any fat that may be adherent.
- 5. Store the graft pieces on a Telfa pad moistened with normal saline.
- 6. Place the skin pieces on the leg ulcer. Leave 2- to 5-mm spaces between grafts as well as between grafts and the ulcer edge to allow drainage of wound secretions (Fig. 33-3).
- 7. Dress the ulcer and grafts with fine-mesh, petrolatum-impregnated gauze (e.g., Adaptic or Xeroform) to cover the whole ulcer, followed by an occlusive dressing with 4 × 4 gauze pads and a compressive dressing.
- 8. Dress the donor site with fine-mesh, petrolatum-impregnated gauze (e.g., Adaptic or Xeroform) followed by dry gauze in at least two layers and light compression with an Ace wrap or Coban (3M, St. Paul, Minn).
- 9. See later for postoperative care.

# **Substitutes for Autographs**

The mathematics of skin loss is very precise; the body cannot afford to lose too much skin surface area before it is fatally compromised. In some cases there may not be adequate skin to harvest or the patient's skin condition may be too poor to supply autografts to cover defects. In these cases substitutes are available to cover defects and allow protection and healing.

Early skin substitutes such as Biobrane, which is a collagenimpregnated fabric that imparts a framework for fibroblasts to adhere

**Figure 33-1** Local anesthetic (without epinephrine) is injected into the donor site, forming wheals 5 to 10 mm in diameter.

to on the wound surface and thus accelerate the healing process, have been available for years. Unlike Telfa dressings, where the slick, shiny side of the dressing touches the wound to prevent adherence, with Biobrane the rough, collagen-bearing fabric side is placed next to the wound and left there until it falls off weeks later. With deep second-degree skin loss this is all that may be needed to stimulate healing.

Heterografts such as pig skin may be used to temporarily stabilize and débride large areas of skin loss that may need temporary coverage until autografting can take place with the patient's own skin.

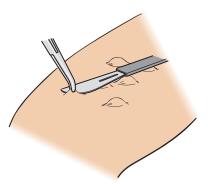

Synthetic skin has undergone remarkable development from the early days of culturing fibroblasts from the foreskins of circumcised infants, to today's modern techniques of growing customized skin using stem cell technology. Currently, the major problem with these grafts is their lack of durability and short life span.

Allografting with banked cadaver skin is the mainstay of burn centers today. It is used for covering large, full-thickness areas of skin loss. There is a good supply of this material, but the potential to spread serious tissue-borne diseases always must be kept in mind and could limit general use.

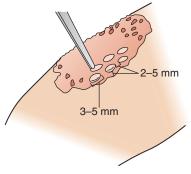

Most of these materials are supplied in sheets, as a mesh, and are ready to be applied using the basic techniques for grafting previously covered. Before using them one must be familiar with all the supplier's recommendations for use.

#### **Complications**

- The most common complication is graft failure.
- Infections at the donor site or the ulcer are rarely reported.
- Deep venous thrombosis (DVT) is a possible complication of this procedure because of immobilization.

**Figure 33-2** Anesthetized skin is grasped with the tissue forceps. Full-thickness pieces of skin 3 to 5 mm in diameter are removed.

**Figure 33-3** Skin pieces are placed on the leg ulcer, with 2- to 5-mm spaces left between grafts as well as between grafts and the ulcer edge to allow drainage of wound secretions.

- Bleeding at the donor site occurs frequently but is almost always minor and easily controlled with local pressure.
- Cosmetic outcome should be considered because grafts heal with a
  permanent studded appearance to the wound, so they work best on
  smaller lesions in less cosmetically sensitive areas such as legs and
  ankles.

# **Postprocedure Patient Education and Care**

- Give the patient a handout on postoperative care. (See the sample patient education form online at www.expertconsult.com.)
- Patients must be placed on *bed rest*, with toilet privileges, with the grafted leg elevated for 7 days.
- The *donor site dressing* can be removed and replaced two to three times a day as needed. Wash gently with soap and water. Cover with petrolatum or antibiotic ointment, followed by the dressing.
- At 7 days after the procedure, the petrolatum gauze covering the ulcer is removed (if wound secretions are profuse, the compresses covering the petrolatum gauze are changed daily). After the petrolatum gauze is removed, a nonadhering dressing is applied and held in place with an elastic bandage. This dressing may be made by impregnating a stockinette with petrolatum ointment, or a commercially prepared product such as Adaptic or Xeroform gauze (bismuth tribromophenate) may be used.
- At 7 days after the procedure, the patient is allowed to ambulate.
- At 14 days after the procedure, the stockinette is removed and the ulcer dressed with gauze as needed.
- Some authorities recommend that low—molecular-weight heparin, or other DVT prophylaxis, be given to patients at high risk of venous thrombosis for 7 to 10 days after pinch grafting.
- Prophylactic antibiotics have generally not been used but could be considered in high-risk situations. If topical antibiotics are used, it is best to avoid those products containing neomycin owing to the high rate of allergic reactions.

#### **Conclusion**

Pinch grafting is a simple therapeutic procedure that may hasten and improve the healing of leg ulcers. The technique is relatively simple, can be performed at the bedside, and requires no special equipment or supplies. This procedure does require a prolonged period of postgraft ambulation restriction. Patients should know about and be prepared for this restricted ambulation. Clinicians should consider pinch grafting as an adjunct to conservative therapy for treatment of leg ulcers, especially when other therapies like the Unna boot have failed. Unna boots do not make a good outer covering dressing for skin grafts because they tend to apply too much compression for optimum vascularization of the new graft.

# FULL-THICKNESS AND SPLIT-THICKNESS SKIN GRAFTS

Every primary care physician who manages wounds will encounter full-thickness skin loss that cannot be closed by conventional suturing methods. One of the best ways to solve these full-thickness skin loss problems is through the use of skin grafting techniques. The cutaneous surgeon possessing the basic skills of skin closure can easily master this most useful procedure. Donor skin reduces the size of the defect and speeds healing time. A properly selected and applied graft creates a minimal donor site defect and contributes to good function and cosmetic results.

#### **Indications**

- Full-thickness abrasions and burns where skin loss creates defects 1 cm or more in width between viable skin edges
- Full-thickness skin loss on areas that have tight skin that cannot be advanced or undermined (e.g., tip of the nose, fingers, and toes)
- Large areas of skin loss that need to be minimized for better function
- To provide essential covering for defects that cannot be closed (e.g., large skin excision sites, full-thickness skin flap donor sites, tendons, cartilage, and bone)
- Areas of skin loss where excessive scarring of secondary granulation tissue may impair function or create adverse cosmetic results

#### **Contraindications**

- Infection at the donor site
- Infection at the recipient site
- Excessive bleeding at the recipient site
- Contamination of the recipient site with imbedded foreign material
- Excessive edema at the recipient site
- Inadequate blood supply to sustain a graft

**NOTE:** Defects that are smaller than the size of a dime (1 cm in diameter) will heal well on their own without the need for grafting. If wounds are contaminated with foreign material or are infected, a delay of the grafting procedure will allow for the recipient site to establish granulation tissue that will better support the graft.

# **Skin Graft Types**

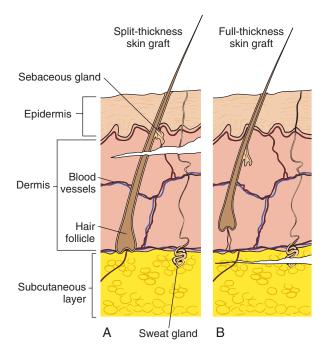

Skin grafts are divided into two categories: split thickness and full thickness (Fig. 33-4):

Full-thickness grafts consist of the epidermis and the entire dermis. Full-thickness grafts are harvested by sharp dissection with a scalpel, and the thickness of the graft is determined by the region of the body where the donor skin originates.

Split-thickness grafts consist of the epidermis and a variable depth of dermis. Split-thickness grafts take only a part of the dermis, leaving the rest of the dermis at the donor site to regenerate. There are three grades of a split-thickness graft: thin (0.005 to 0.010 inch), medium, and thick. The thickness is varied by the downward pressure the surgeon exerts on the dermatome handle, or by a steeper angle applied to the cutting blade. Mechanical dermatomes are available that have an adjustable gate, or a preset thickness setting, that will determine graft thickness (Fig. 33-5).

Whether the surgeon uses a free-hand shave technique or a preset dermatome, it takes practice to produce skin grafts of appropriate thickness.

**NOTE:** The tendency of the novice operator is to produce thicker split-thickness grafts than intended, even with the mechanical dermatome set on the thinnest settings.

**Figure 33-4** Free skin grafts are divided into two main types: split-thickness (**A**) and full-thickness (**B**).

#### Split-Thickness Grafts

#### ADVANTAGES

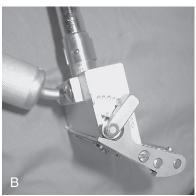

- Split-thickness grafts can be "meshed" and made to cover large areas of skin loss. In this technique, small slits are cut in the graft similar to the holes in a pie crust, allowing the sides of the graft to be stretched by an expansion ratio of 1 to 1½ times (Fig. 33-6).
- Thicker grafts can be placed in a mechanical mesh maker (Fig. 33-7) to form a uniform mesh pattern that covers large areas of skin loss from full-thickness burns. Extensive meshing promotes drainage of blood and serum from under the graft and improves success of donor skin revascularization.
- Very thin grafts (0.010 to 0.015 inch) vascularize quickly and heal much more rapidly.
- Split-thickness grafts tend to contract as they heal, thus drawing down the size of the original defect.
- Donor sites heal more rapidly.
- Grafts require less blood supply to survive and may be the best choice for sites where vascularization is less than optimal.

The thickness of the graft can vary to satisfy the need for wear, appearance, hair growth, and speed of healing. Thin grafts heal rapidly but are not as cosmetically pleasing. Grafts thicker than 0.015 inch look better and resist wear better but heal more slowly.

#### **DISADVANTAGES**

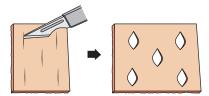

- Split-thickness skin grafts are not as resistant to trauma and can be injured easily in areas of friction and wear.
- They are less like normal skin in color, texture, suppleness, and hair growth. The mesh pattern is permanent and is not used in cosmetically sensitive areas such as the face or anterior neck.
- Meshing or "pie crusting" causes additional scarring and skin hypertrophy.
- Split-thickness grafts do not germinate over bone without periosteum, or cartilage without perichondrium.
- A dermatome must be used; for large grafts, an operating suite is necessary.
- Free-hand technique produces only postage stamp-sized grafts.
- These grafts do not work well over joints because they are more likely to cause contracture and restriction of the joint.

**Figure 33-5 A,** Adjustable-thickness motorized dermatome. **B,** Adjustment lever on the motorized dermatome that cams the blade up or down to control the thickness of the skin graft. **C,** Duval battery-powered dermatome with disposable, fixed-depth and fixed-width, detachable head.

**Figure 33-6** Split-thickness grafts can be expanded by "pie crusting" or cutting small slits in places that need expansion. This can expand a graft by 50% over the original size.

**Figure 33-7 A,** The skin graft is placed on the disposable clear plastic template with the dermis side resting on the grooves of the template. **B,** The handle is turned clockwise, rolling the graft through the press. A uniform meshed graft emerges on the opposite side. Meshing allows a 2-inchwide graft to expand to cover a defect of 3 inches (1:1.5 ratio) and facilitates drainage of blood and fluids that may accumulate under the graft.

### **Full-Thickness Grafts**

#### **ADVANTAGES**

- Full-thickness grafts match normal skin contours, color, and texture better than any other form of graft and are more aesthetically pleasing over time.
- They undergo *less postoperative contracture* and will not influence the size of the defect.
- Thick grafts resist friction and wear better than the thinner grafts.
- Full-thickness grafts can be used to cover bone without periosteum and cartilage without perichondrium.

#### DISADVANTAGES

- Full-thickness grafts cannot be used to cover large areas without carrying their own blood supply.
- Large full-thickness donor sites must be covered with splitthickness grafts to heal.
- Full-thickness grafts need a good supply of blood at the recipient site to survive.
- Thick grafts do not contract in total diameter with healing like split-thickness grafts do.
- Full-thickness grafts take the longest time of any graft to vascularize.
- The size of the donor site is determined by the defect size, and the graft cannot be meshed to expand its surface coverage.

#### **Equipment**

- Dermatome
  - Adjustable type with thickness settings, flexible shaft, and external power (see Figs. 33-5A and B)
  - Battery-powered, disposable-head type (see Fig. 33-5C)
- Sterile tongue blade
- 5 to 10 mL sterile mineral oil
- Petrolatum-impregnated gauze, Tegaderm (3M), or fine-mesh gauze
- Minor surgical tray
- 5-0 suture (polyethylene or Vicryl)
- Skin stapler if sutures are not used
- Steri-Strips
- Kerlix roll
- Ace wrap, Coban, or elastic stockinette
- No. 10 or larger blade or a razor blade
- Two Adson tissue forceps

- 5-inch Halsey needle holder
- 4-inch curved iris scissors
- 6-0 or 5-0 nylon sutures (monofilament, not braided)

#### **Donor Sites**

# **Full-Thickness Grafts**

See Figure 33-8.

- Postauricular area
- Supraclavicular area
- Suprapalpebral area
- Antecubital area
- Volar wrist area
- Lower abdominal area
- Inguinal area

#### Split-Thickness Grafts

See Figure 33-9.

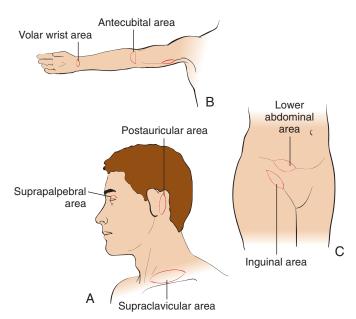

- Posterior lateral thigh
- Superior buttocks
- Anterior abdomen
- Anterior thigh
- Inner surface of the upper arm for hairless skin
- Flexor surface of the forearm

**NOTE:** Facial defects should be repaired with full-thickness grafts because these grafts cause less cosmetic disruption. Never use skin for the face from areas below the clavicle because these grafts do not match in color or texture and they contain hair follicles, resulting in lifelong deformity.

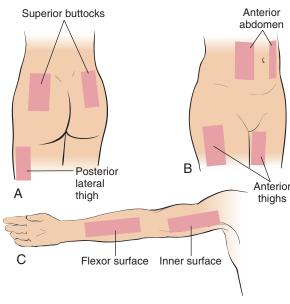

# **Techniques**

#### **Full-Thickness Grafts**

- 1. Make sure no active folliculitis or cellulitis exists close to the donor site.
- 2. Prepare the skin for surgery using aseptic technique.
- 3. Drape the donor site.

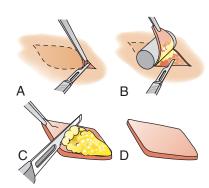

**Figure 33-8** Potential harvest areas for full-thickness grafts. **A,** Head. **B,** Arm. **C,** Lower abdomen and inguinal areas. Do not use grafts from areas shown in (**B**) and (**C**) to graft the face, head, and neck (**A**). The color will never match and a permanent defect will remain.

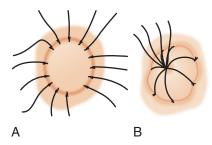

**Figure 33-9** Potential harvest areas for split-thickness grafts. **A,** Posterior buttocks and lateral thigh. **B,** Anterior abdomen and thighs. **C,** Hairless areas of the arm.

- 4. Infiltrate the skin to be transferred with lidocaine without epinephrine for anesthesia.
- 5. Remove a fusiform piece of skin large enough to cover the defect without creating tension (Fig. 33-10A and B).
- 6. Remove as much subcutaneous fat as possible without button-holing the graft (Fig. 33-10C and D).
- Place the graft dermis side down on a saline-soaked gauze pad until ready for transfer.
- 8. Trim the graft to fit the defect.
- 9. Suture the graft into the defect, taking care to notice the skin lines and skin edges (Fig. 33-11A).
- 10. Use polyethylene suture, staples, or Steri-Strips.
- 11. Care must be taken to use the suture size and technique that will result in the least damage to the edges of the skin graft (small premium needles [size P-3] and suture 5-0 or less). Excessive bleeding at the edges will allow blood to flow under the new graft and prevent adherence of the graft.
- 12. A stent dressing best secures the graft (Fig. 33-11B).
- 13. Close the donor site in the usual fashion with sutures or staples. If the donor site cannot be closed without excess tension, a split-thickness graft can be used to cover it.

**Figure 33-10** Full-thickness grafts should have all the subcutaneous fat removed before being placed on the graft site. **A,** Excising the graft. **B,** Using a small cotton roll to aid in keeping the graft flat. **C,** Removing the subcutaneous fat from donor skin. **D,** Graft skin ready to be applied.

**Figure 33-11** Grafts can be secured best by using a stent. Suture tails are left long at the time of attachment of the graft (**A**), then tied over the dressing (**B**) to provide pressure and anchor the graft in place. An initial layer of nonadherent material is applied, or the graft may be lubricated with antibiotic ointment to prevent the gauze stent from sticking.

14. Place a nonadherent dressing on the donor site and treat as a laceration.

#### **Split-Thickness Grafts**

#### HARVESTING TECHNIQUES: DERMATOME

- 1. Make sure no active infection or atrophic skin diseases exist on or near the donor or recipient site.
- 2. Prepare and drape the area with surgical scrub and drapes.
- 3. Ready the dermatome by setting the desired thickness on the gauge. Usually the best intermediate setting is the thickness of a scalpel blade. Thin grafts should transmit light like frosted glass. Disposable dermatome heads will produce thin grafts; the operator simply needs to decide on the blade width because various heads have various widths.
- 4. Anesthetize the skin to be harvested with local or regional anesthesia for small grafts. General anesthesia can be used when the areas to be grafted are large.
- 5. *Place a thin film of sterile mineral oil* on the skin that will be run through the dermatome. This lubricates the surfaces and helps maintain a uniform thickness.
- 6. Have an assistant use the sterile tongue blade to depress the skin in front of the dermatome and provide countertraction to straighten out any wrinkles in the skin.
- 7. Start the dermatome and approach the skin at a fairly steep angle until the blade catches the skin and begins cutting. When this happens, flatten the angle so the undersurface of the dermatome is aligned perfectly parallel with the skin surface. Downward pressure on the handle will place the blade deeper in the dermis and produce a thicker graft (Fig. 33-12).
- 8. The split-thickness graft will bunch up behind the blade and an assistant will need to *grasp the leading edges of the graft* and gently lift them straight up (the way a thin slice of cheese is lifted from a cheese cutter to keep it from bunching up). The total length of the graft can be determined easily as it is lifted off the blade.

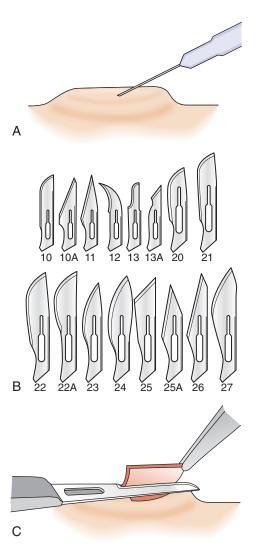

Figure 33-12 Battery-powered dermatome at the correct cutting angle.

- 9. When the desired graft length is reached, release downward pressure on the dermatome handle and point the blade in a steep upward angle, severing the graft.
- 10. Spread the graft out carefully, with the dermis side down, on saline-soaked gauze. In the case of extremely thin grafts, the skin can be floated on the surface of sterile saline in a basin before being transferred to the recipient site.
  - **NOTE:** The shiny side is always the dermis side (vs. epidermis) and must go next to the vascular surface of the recipient site; otherwise it would be like laying grass sod upside down.
- 11. The donor site is dressed with Tegaderm or Adaptic, or Biobrane, or Xeroform gauze, or fine-mess gauze, which is left in place until it falls off in about 2 weeks. A gauze wrap and an Ace bandage can further protect the wound and reduce scar hypertrophy.

**HARVESTING TECHNIQUES: FREE-HAND.** This technique is well suited to the outpatient setting or emergency department, where small areas of skin loss elude conventional closure and require grafting.

 A half-dollar-sized (3 × 3 cm) area on the forearm or thigh is infiltrated with 2% plain lidocaine without epinephrine, prepared with antiseptic solution, and draped for surgery (Fig. 33-13A).

**Figure 33-13** Free-hand split-thickness graft. **A,** Infiltration with local anesthesia will slightly raise the skin, making cutting easier. **B,** Scalpel blades of various sizes. **C,** The large scalpel blade is held at a shallow angle to the skin, and the graft is shaved off to a desired length.

**Figure 33-14** The Derma-blade is bent in a U-shape between the thumb and forefinger in preparation for harvesting a free-hand split-thickness graft. Widening the distance between the thumb and forefinger will widen the strip of skin being harvested. T-shaped gripping bars at each end of the blade improve control. (Courtesy of American Safety Razor, Cedar Knolls, NI.)

- 2. Using a scalpel blade with a long straight cutting edge, like the no. 20, 21, or no. 22 in a scalpel handle (Fig. 33-13B), shave the skin at the desired thickness with a gentle slicing motion (Fig. 33-13C). A thin, standard double-edged razor blade or a specially prepared razor blade called a Derma-blade (American Safety Razor; Cedar Knolls, NJ) can also be used (Fig. 33-14). Both blades are straight when not in use, and are grasped between the thumb and index finger and gently bent into a U-shaped arc. The closer the thumb and index finger are drawn together the narrower the strip of skin will become. The Derma-blade is more expensive than a standard double-edged razor blade, but it has the advantage of being completely sterile and much safer to use. The graft is taken by applying light downward pressure on the blade and moving it side to side in smooth oscillating strokes. The greater the downward pressure on the blade the thicker the graft.
- 3. Widths up to 2 cm can be removed up to the length needed.
- 4. The skin can be transferred directly to the defect and sutured in place like any other split-thickness graft.

# Recipient Site Preparation and Graft Stabilization

- 1. In the case of full-thickness grafts, *meticulous hemostasis* is the key to graft survival. *Bipolar* cautery (as opposed to the monopolar cautery generally used) is the best way to achieve homeostasis with very little thermal damage.
- 2. The full-thickness *graft must be tailored precisely to the defect* at the time of placement, whereas split-thickness grafts may overlap the margins.
- 3. The survival of split-thickness grafts depends on the growth of capillary beds into the raw undersurface of the graft. This may take several weeks of preparation to allow granulation tissue to develop. Try to use natural methods of débridement and capillary bed enhancement because enzymatic débriding agents will attack the graft as well.

Figure 33-15 Split-thickness skin graft 10 days after surgery.

- 4. The graft must *not move* during the period of revascularization. The graft can be secured with a 6-0 or 5-0 monofilament suture. One tail of the suture is intentionally left twice as long as the diameter of the defect so a stent dressing can be tied over the graft (see Fig. 33-11). The dressing will stay in place for 7 to 10 days. Avoid the temptation to look under the dressing during the healing processes.
- 5. Use as few sutures as necessary. Simple interrupted suture with monofilament material is the best tolerated. Do not put too much tension on the graft or the sutures. If more stabilization is needed, Steri-Strips can be used. Some surgeons report good success with Steri-Strips alone. Dermabond, a commercial dermal adhesive, can stabilize fragile grafts; however, care must be taken not to allow the adhesive to flow between the graft and recipient site, which will prevent adherence.
- 6. In the case of large split-thickness grafts, skin staples can be used. This is a more rapid method of attachment and is relatively atraumatic (Fig. 33-15).
- 7. Large skin grafts may require a "pie crust" maneuver to vent bubbles or blood from under the graft itself. Small holes can be cut in the graft with fine scissors or a scalpel to let out the fluid (see Fig. 33-6).
- 8. Cover the graft with nonadherent material like Adaptic, Biobrane, Xeroform gauze, or Telfa. Make sure the new graft stays moist and out of the ambient air for extended periods. Cover the nonadherent material with saline-moistened gauze and at least two layers of protective gauze wrap and a light compressive dressing of Ace wrap or Coban.

The dressings are not changed for the first 24 to 48 hours after graft placement unless soiled or bloody; then, for the next two daily outer dressing changes moistened gauze is replaced over the nonadherent dressing. It is best not to disturb the nonadherent dressing in direct contact with the graft to prevent movement of the new graft.

9. The graft *must be protected from trauma* and from loss of contact with the vascular bed. Some cutaneous surgeons prefer to roll a cotton-tipped applicator over the surface of the new graft, rolling from the middle of the newly applied skin to the outside. This expresses unwanted blood, fluids, or air bubbles that will lift the healing graft away from the recipient bed.

#### **Common Errors**

- Placing the wrong surface of the graft against the donor site. Care must
  be taken at all times to ensure that the graft is not turned over
  in transferring it from the donor site to the recipient site. Splitthickness grafts are the most susceptible to this mistake.
- Allowing split-thickness grafts to dry out between harvesting and placement. The graft should be kept in moist gauze or a small basin of saline. Blot, do not rub, the surfaces of the graft.
- Causing excessive bleeding to the donor site before graft placement.
   Excessive débridement or wiping of the site with antiseptic-saturated gauze may cause bleeding that will lift the graft from the surface after placement and encourage infection.
- Not removing large air bubbles. Air bubbles can become trapped under the graft during the placement process and before application of the dressing. Care must be taken to remove such bubbles or fluid pockets.
- Not removing all the fat and subcutaneous tissue from the dermal side of a full-thickness skin graft. The dermal side of a full-thickness graft should be free of any material that will block the migration of vascular elements into the skin graft.
- Allowing edema or venous stasis to occur in the grafted extremity.
   Edema and vascular congestion will cause the buildup of fluid under the graft and lift it away from the recipient site.
- Attempting to remove an adherent covering in direct contact with the graft in less than 7 days. Dressing edges can be trimmed when they spontaneously lift away from the surgical site, but the dressing should never be pulled off.

 Loose-fitting dressings. Loose dressings will cause excessive shear forces on the skin graft during the 7- to 14-day healing process. Movement of the graft will impede healing and adherence.

# **Complications**

The major complication of skin grafting is *infection* at the donor site (causing it to become a full-thickness defect) and *loss* of the graft at the recipient site (causing another full-thickness defect). The use of prophylactic antibiotics cannot make up for poor planning and bad surgical technique; therefore, it is important to approach full-thickness skin loss with proper preparation.

# SKIN STAPLING

David James

In certain body areas, when performed with care, skin stapling provides a rapid and simple alternative to other methods of skin closure and wound repair. Clinical experience with stapling now spans decades, and improved equipment, such as absorbable staples, is being introduced constantly. A variety of staplers with specific features for the purpose to which they are being applied are available. For example, staplers designed for small lacerations may hold only 5 fine staples, whereas staplers for general-purpose closure may hold up to 35 heavier-gauge staples.

#### **ADVANTAGES**

The final result of a stapled wound depends directly on its location, the condition of the wound being stapled, and operator experience. The best cosmetic results are seen in clean, uninfected linear wounds of the scalp, torso, and proximal extremities that have some degree of a subcutaneous fat "bed" and that are not under undue tension. Poorer results occur when the wound is macerated, ragged, infected, under tension, or placed directly over a bony prominence with thinner skin.

Numerous studies have supported stapling as an acceptable alternative to suture closure, and in some studies a lower rate of infection after closure has been found with stapling. Staples are generally well accepted by patients, and, in most cases, it is a much faster procedure than suturing. Well-placed staples evert the wound edges optimally and place less tension on wound edges than sutures. Surgical stainless steel staples are less "reactive" than sutures and potentially result in less postclosure inflammation and infection. Staple ends do not completely meet in the deeper tissues, thus resulting in less tissue constriction; this may also promote a lower infection rate.

#### **DISADVANTAGES**

Stapling has the potential to provide a result inferior to suturing. Staples certainly do leave larger puncture scars proportional to the time they remain in the wound, and the cost—benefit ratio of using a stapling device in smaller wounds is not advantageous. Recycling of the used devices are also problematic because most are made of plastic and are for single-use only.

# **INDICATIONS**

- To secure skin grafts or repair wounds whose edges are easily approximated and not under undue tension
- Long, linear wounds of the scalp, proximal extremities, or the torso where cosmesis is not a concern

## **CONTRAINDICATIONS**

 Facial or neck tissue, or in areas where there is an inadequate subcutaneous base

- Over small mobile joints of the hand and foot, soles and palms, or any other location where the staples may interfere with function of a body part
- In wounds that are macerated or infected, or over areas of large tissue loss, unless the subcutaneous tissues may be easily approximated after undermining and use of buried deeper sutures to help approximate the skin edges

#### **E**OUIPMENT

- Skin hooks or two pairs of fine Adson forceps
- Skin stapler with appropriate-gauge staples (heavier gauge for longer wounds over thicker tissue, lighter gauge for smaller wounds)
- Sterile surgical skin preparation solution, sterile drapes, gloves for the operators
- Local anesthetic appropriate for the area to be repaired
- Suture kit with appropriate sutures on standby, in case deeper sutures need to be inserted to take tension off the skin edges
- Staple remover (usually given to patient if another practitioner will be removing the staples)

# PREPROCEDURE PATIENT PREPARATION

Community standards or facility type will dictate the nature and extent of any consent forms involved. In all cases, the patient should be informed about the procedure to close the wound, the intent to use staples, the relative advantages and disadvantages of staple use in his or her particular wound, how to care for the repaired wound, and when to return for recheck and/or suture removal.

# **TECHNIQUE**

- 1. The help of an assistant to hold the skin edges together for the stapler operator is often useful during the procedure (Fig. 34-1).
- 2. Prepare and drape the wound in the usual fashion.
- 3. Don sterile gloves.
- 4. Anesthetize the area to be repaired with injectable lidocaine 1% or 2% with or without epinephrine. Topical anesthetics (e.g., a solution of lidocaine, epinephrine, and tetracaine) may be used as an alternative to injectable anesthetics.
- 5. If there is tissue loss or if the wound is gaping, undermine the edges of the wound and close the deeper layers with buried absorbable sutures. The skin edges should be well approximated and under no tension before stapling is performed.
- 6. Have assistant (if present) pick up the skin edges of the wound in front of the stapler with the skin hooks/forceps, and gently hold them together and slightly elevate them.
- 7. Start at one end of the wound, pointing the stapler toward the opposite end. Position the stapler guide (usually an arrow) over the laceration and press the stapler gently down onto the skin.

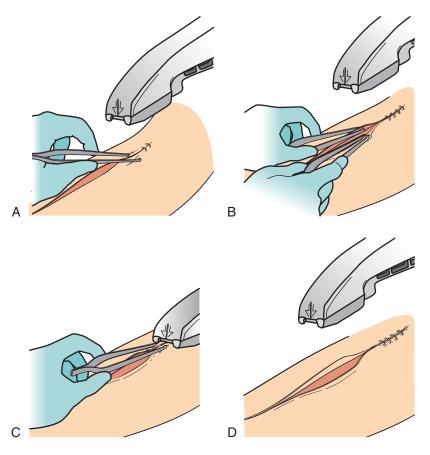

Figure 34-1 Use of a skin stapler. Approximate skin edges so they are slightly everted with one forceps (A) or two forceps (B). Position the instrument lightly over the everted skin edges, aligning the stapler arrow with the incision (C). Pressing down on the instrument too heavily may make staple removal difficult. Squeeze the trigger quickly and firmly until the trigger motion is halted (D). Release the trigger and back the instrument off the staple.

Squeeze the trigger, placing one staple. *Do not release the trigger*, but pull up gently on the stapler. This will pull up the wound edges.

- 8. Release the stapler trigger and remove the stapler.
- 9. Replace the guide over the laceration, and repeat step 6.
- 10. Alternate step 7, followed by step 6, until the end of the wound is reached. If there is a "dog-ear" of excess tissue, excise with forceps and iris scissors and place final staples.
- 11. The distance between staples depends on the operator and his or her experience, but the wound margins should be approximated without gaps when complete. Some clinicians prefer to start closing at the middle of a wound, lessening the chance of dog-ears.
- 12. A lone operator can approximate the skin edges with a single forceps by pulling the skin edges together before placing a staple, or by placing the thumb and forefinger of the non-operating hand along the edges of the skin to pull them together.
- 13. After stapling is complete, reclean the wound and place an appropriate dressing.
- 14. Arrangements for follow-up and staple removal should be made. In general, staples should remain in place for 8 to 10 days. Stapled scalps may be washed after staple placement if necessary.
- 15. Removal of staples is best accomplished by a staple remover that bends the staple arms up and out of the skin (Fig. 34-2). A hemostat may also be used to pry up each staple arm.

# **COMPLICATIONS**

Complications, although rarely reported, include dehiscence, poor cosmesis, infection, and hematoma. These are similar to the complications seen with a sutured wound.

# SUBUNGUAL HEMATOMA EVACUATION

Rebecca Beach

Injuries to the nail bed and fingertip are the most common injuries to the upper extremity. Most common among these is a subungual hematoma, which results from a direct blow to the fingernail or a squeezing-type injury to the distal finger, causing bleeding into the space between the nail bed and the fingernail itself. Intense pain can result from the pressure generated by such a hematoma. Evacuation of the hematoma can produce significant relief and can be performed safely in the outpatient setting. Toenails can be treated in the same fashion. Evacuation of a hematoma may or may not prevent the eventual spontaneous avulsion of the nail that results from some hematomas. Patients should be made aware of this possibility. Radiographs may be necessary and, if a fracture is documented, antibiotics may be indicated because this would then essentially be an open fracture.

# **INDICATION**

A visible, painful hematoma beneath the involved nail (Fig. 35-1) requires treatment.

# **CONTRAINDICATIONS**

- Crushed or fractured nail bed or fracture of distal phalanx.
- Hematomas involving greater than 50% of the nail may indicate laceration of the underlying nail bed. (Removal of the nail and repair of the laceration is recommended by some experts to avoid a post-traumatic nail deformity. Others recommend leaving the nail in place as a splint. The patient should be warned that the nail may be deformed unless the nail bed is examined and treated.)

# **EQUIPMENT**

- Alcohol lamp or Bunsen burner (or cigarette lighter), metal paperclip, and forceps or hemostat
- Or battery-operated cautery unit
- Or 18-gauge needle or no. 11 scalpel
- Or automatic drill device (Dremel tool, dental burr, or Path-Former device)
- Or radiofrequency or electrocautery unit with needle or pointed electrode

# **TECHNIQUE**

- Wash the digit as thoroughly as possible with an antibacterial soap to decrease the possibility of contamination of the hematoma and subsequent infection.
- 2. Consider a digital block with lidocaine without epinephrine because any pressure on the area can be painful.

- 3. Create a hole in the nail directly over the center of the hematoma to allow decompression.
  - Paperclip method. Partially straighten a metal paperclip, grasp it with the forceps, and heat it over the alcohol lamp, Bunsen burner, or lighter. Place the heated clip firmly on the nail, allowing it to melt the tissue for a few seconds until the nail is completely perforated (Fig. 35-2).
  - Cautery method. In similar fashion, apply battery cautery tip to the nail and create a hole in the nail bed (Fig. 35-3). Some electrocautery units may work, but there is often too much keratin in the nail for it to be effective.
  - Drill method. Twist a large-bore needle or scalpel between your fingers gently in one place to create a 1- to 2-mm hole over the central area of the hematoma. A 2-mm, sharp, disposable punch biopsy unit can also be tried. Alternatively, a drill device (Dremel tool, dental burr, or PathFormer device) may be used. The only drawback to this method is that any pressure on the nail can cause pain, so proceed gently.

In the first two procedures mentioned, the heated tip is cooled by the hematoma on perforation of the nail, thereby preventing injury to the nail bed. This effect is maximal in the center of the hematoma, where the distance between nail and tissue is greatest. Similarly, with the drill technique, the tip of any drill/needle/scalpel will not touch sensitive tissue if it is placed in the center of the hematoma. The hole created in the nail should be of sufficient size so as not to close off within a few hours (adequate size is 1 to 2 mm). Elevation of the finger, cool compresses, and a simple bandage are recommended during the first 12 hours. Use of antibiotic ointment can serve dual purposes—to moisturize (minimizing blood clotting so that the hematoma will drain maximally and prevent blood from adhering to the bandage) and to minimize infection. Because patient anxiety can be severe, passing the needle through the fibers of a 4  $\times$  4 gauze so that the patient cannot visualize it may make the drilling procedure more tolerable for a child.

# **COMPLICATIONS**

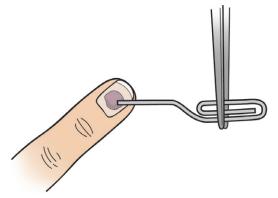

- Infection of the remaining hematoma
- Pain
- Inadvertently lacerating the nail bed
- Not recognizing a fracture beneath the hematoma

# **CAUTIONS**

 Neither the drill method nor the two heat methods by themselves should be painful, but the hematoma itself may be exquisitely tender, so the digit should be grasped gently, proximal to the injury.

Figure 35-1 Subungual hematoma.

**Figure 35-2** Heated paperclip is placed directly over the hematoma to create a perforation of the nail.

**Figure 35-3** Cautery unit may be used to perforate the nail and evacuate the subungual hematoma.

- Either a local anesthetic or ethyl chloride may be used before these methods, if desired, to decrease pain. However, ethyl chloride is flammable and should not be used during or immediately before the cautery method or very close to the flame of the paperclip method. Holding the area in ice water is safer. Consider a digital block.
- Artificial acrylic nails may also be flammable.

# TICK REMOVAL AND PREVENTION OF INFECTION

David James

Persons frequenting outdoor areas may be exposed to ticks. Ticks often lurk in tall grasses or in overhead branches, and will attach themselves to persons passing by them in search of a blood meal. Although most tick bites are harmless, ticks may be the vectors of several significant diseases. Because it is impossible to identify in the field whether a tick carries an infectious disease, it is good medical practice to remove all ticks found on human skin promptly. Ticks feed slowly, and several hours of attachment are thought to be required for transmission of tick-borne illnesses.

#### **DISEASES TRANSMITTED BY TICKS**

Ticks have eight legs and are members of the class Arachnida. Ticks belonging to the families Argasidae (soft ticks) and Ixodidae (hard ticks) are able to act as disease vectors to humans. The ixodid ticks *Dermacentor* and *Ixodes* are most likely to be encountered by humans in North America, and they can transmit microorganisms hematogenously during all phases of their development. See Box 36-1 for a list of tick-borne diseases.

Ticks have powerful mouthparts to break the skin of their hosts and enable a blood meal. The saliva of the tick has anticoagulant properties to keep blood flowing. Pathogens in the gut of the tick migrate to the tick's salivary glands, and thus are transmitted parenterally to the host during feeding. Generally, a tick must be attached for longer than 8 hours for successful transmission of disease.

Two of the tick-borne diseases bear special mention. *Tick-bite paralysis* is a serious illness that presents as an ascending neuromuscular paralysis, similar to Guillain-Barré syndrome. The paralysis is caused by envenomation of the host with a salivary neurotoxin secreted in the saliva of certain gravid *Dermacentor* ticks. Resolution of the paralysis occurs after removal of the often-overlooked tick.

Lyme disease is a fairly common illness affecting the cardiovascular, musculoskeletal, neurologic, and dermatologic systems. It is often seen in children and adults who spend time outdoors. Lyme disease is caused by the spirochete Borrelia burgdorferi, and is transmitted to humans by the bite of the hard Ixodes tick. White-footed mice and white-tailed deer are the major reservoirs for B. burgdorferi. This disease is becoming prevalent throughout northeastern North America, and is worth including in the differential diagnosis of unusual rashes, fevers, myalgias, and arthralgias. It is best diagnosed by enzyme-linked immunosorbent assay (ELISA) testing of serum for specific antibodies to B. burgdorferi. A Lyme disease preventative vaccine is now commercially available (LYMErix), and may be appropriate for those individuals living in high-prevalence locations who spend a great deal of time outdoors. Treatment of Lyme disease is discussed in the section on Complications and Disease Prevention. See Table 36-1 for a synopsis of presenting features of other tick-borne diseases.

Recently, the tick Amblyomma americanum has been associated with an erythema migrans-like rash in patients from the southeast-

ern United States. This condition has been termed southern tick-associated rash illness (STARI). It is distinct from Lyme disease because it is not caused by the spirochete B. burgdorferi, and some cases have been identified with a novel spirochete, Bornelia longestari. Treatment is with antibiotics, as listed in the section on Complications and Disease Prevention.

Hard ticks are best removed mechanically. Care must be taken to remove the tick's mouthparts, which will be firmly embedded in the host. The head and mouthparts may separate from the tick's body if not removed properly, thus increasing risk of disease transmission. A punch biopsy of the tissue surrounding the mouthparts may then be necessary. *Home remedies*, such as the placement of oil on the tick to smother it or burning the tick with a hot match or cigarette, are not recommended. Both techniques have the potential to cause the tick to regurgitate its blood meal and cause significant inoculation of disease pathogens.

#### **EOUIPMENT**

- Blunt curved forceps or tweezers
- Rubber gloves
- Povidone-iodine scrub and solution
- Normal saline specimen container or culture medium (optional)
- Gauze and bandage

In addition, for difficult removal or retained mouthparts:

- Punch biopsy equipment for 3- to 6-mm punch as appropriate
- Iris scissors
- Lidocaine 0.5 mL in syringe with 30-gauge needle
- Aluminum chloride solution 6.25% on a cotton-tipped swab (optional)
- 5-0 nylon suture and needle driver (optional)

# Box 36-1. Tick-borne Diseases

Babesiosis

Human granulocytic and monocytic ehrlichiosis

Lyme disease

Q fever

Rocky Mountain spotted fever

Tick fever

Tick-bite paralysis

Tularemia

Typhus

TABLE 36-1 Common Tick-Borne Diseases and Their Management					
	Lyme Disease	Ehrlichiosis	Rocky Mountain Spotted Fever	Tularemia	
Pathogens	Borrelia burgdorferi	Ehrlichia chaffeensis Ehrlichia ewingii	Rickettsia rickettsii	Francisella tularensis	
Geographic distribution in continental United States	Northeast and upper Midwest	South, Southeast, and Midwest	Southeast, Atlantic Coast states, Midwest	South and Midwest	
Presenting symptoms	Erythema migrans, fatigue, myalgias, arthralgias, headache, fever, chills, neuropathies	Fever, chills, headache, myalgias	Macular rash, fever, myalgias, vomiting, fatigue, headache	Fever, chills, headache, cough, diarrhea, fatigue, vomiting, sore throat; contact with mice is a risk factor	
Initial laboratory findings	Nonspecific; convalescent serology positive at 4–6 wk for antibodies to Borrelia	Leukopenia, thrombocytopenia, elevated liver aminotransferases; confirmatory convalescent serology at 1–2 wk	Leukopenia, thrombocytopenia, elevated liver aminotransferases, hyponatremia; confirmatory convalescent serology at 7–10 days	White blood cell count often normal, elevated erythrocyte sedimentation rate; confirmatory convalescent serology at 2 wk	
Treatment	Doxycycline, tetracycline, amoxicillin-clavulanate, levofloxacin, erythromycin	Doxycycline, chloramphenicol, rifampin	Tetracycline, doxycycline, chloramphenicol	Streptomycin, gentamicin, tetracycline, chloramphenicol, fluoroquinolones	

# **TECHNIQUE**

- Gently paint the surrounding area with povidone-iodine solution.
- 2. With blunt forceps, tweezers, or gloved fingers, grasp the tick as close to the skin surface as possible and pull upward and perpendicular with steady, even pressure (Fig. 36-1).
- Do not twist or jerk the tick because this may break off mouthparts.
- 4. Never squeeze, crush, or puncture the body of the tick because its fluids may contain infectious agents.
- 5. The tick may be sent for microscopic analysis of the *Borrelia* spirochete or cultured for other organisms.
- Disinfect the bite site with povidone-iodine scrub or antibacterial soap.

**Figure 36-1** Technique of tick removal. **A,** Apply the instrument perpendicular to the skin, encompassing the tick. **B,** Pull upward with a steady, even pressure.

In cases of a particularly tenacious tick, retained mouthparts, or high-risk endemic areas, perform the following technique:

- 1. Disinfect the area with antibacterial soap. Infiltrate the area beneath the bite with lidocaine.
- 2. Apply the punch biopsy instrument perpendicular to the skin so that it encompasses the tick. Stretch the skin on each side of the lesion. Advance the biopsy punch downward with moderate pressure, using a clockwise–counterclockwise twisting motion. Penetration through the epidermis and dermis is confirmed with a marked decrease in resistance (see Chapter 32, Skin Biopsy).
- Remove the punch. Lift the biopsy specimen with forceps and cut the pedicle with iris scissors. Submit the tissue for histologic study.
- 4. Disinfect the area again and apply pressure with gauze. If adequate hemostasis is not accomplished, cauterize with aluminum chloride solution or close with suture. Apply bandage.

#### **COMPLICATIONS AND DISEASE PREVENTION**

Local complications of tick removal may include transient *bleeding* or *cellulitis*. Bleeding is managed by locally applied pressure, whereas cellulitis is prevented by attention to area cleanliness and follow-up care.

As Lyme disease is becoming more prevalent throughout North America, prophylactic antibiotics after a tick bite seem a reasonable approach to infection prevention. After tick removal, a 10-day course of antibiotics is recommended. Choices include doxycycline 100 mg orally twice daily or tetracycline 500 mg orally four times a day (for adults, and children 10 years of age and older); amoxicillinclavulanate 400 to 875 mg orally twice daily; levofloxacin 500 mg orally daily; or erythromycin 125 to 500 mg orally four times a day.

# TISSUE GLUES

Rebecca Beach

Cyanoacrylates have been in widespread use outside of the United States for years, and the U.S. Food and Drug Administration (FDA) approved their use for repair of incisions and lacerations in 1998. The agents combine cyanoacrylates and formaldehyde. Some have added plasticizers for extra strength and flexibility. Dermabond (2-octylcyanoacrylate; Ethicon Corp., Norwood, Mass) is available in small, single-use, glass vacuum vials, and it forms a polymeric bond across apposed tissue edges on contact with moisture or air. There are several newer brands, including SurgiSeal (Adhezion Biomedical, Wyomissing, Penn) and LiquiBand (MedLogic Global, Ltd., Plymouth, United Kingdom). Over-the-counter cyanoacrylates such as Super Glue and Crazy Glue are somewhat weaker and are not FDA approved for this indication but are used by many patients at home. The latter preparations have more difficulty binding to a moist surface. Cosmesis with tissue glues is comparable or superior to sutures, and there is much greater acceptance, especially with children. The products have antimicrobial properties and negligible tissue toxicity and are easily applied. They significantly decrease wound repair time.

# **INDICATIONS**

- Nonmucosal laceration or incision repairs
- Facial, scalp, torso, or extremity wounds
- After deep suture placement if skin tension is minimal
- Wounds less than 8 cm (gap <0.5 cm)
- As an alternative to 5-0 or smaller suture
- Removal of foreign bodies in ear or nose (physicians can apply a small drop of glue on the wooden end of cotton swab, touch the object for 30 seconds, and remove)
- Repair of lacerated nails or nail beds
- Because there is more scarring the longer sutures are left in, consider removing any sutures a few days ahead of schedule after the wound has sealed over and applying a tissue glue to keep the wound edges together

#### **CONTRAINDICATIONS**

- Mucosal lesions
- Significant wound margin tension
- Noncompliant patient
- Heavily contaminated wounds requiring débridement
- Human or animal bite or scratch wounds
- Puncture wounds
- Stellate, jagged, or crush wounds
- Wounds on axillae, perineum, or feet
- Hand or joint lacerations (in which repetitive movement or washing can weaken bond)

# **ADVANTAGES**

- Faster than suturing or stapling
- Less painful

- · Less need for painful injectable anesthetic
- As effective as suturing in appropriately selected patients
- A lower infection rate compared with staples and sutures (according to some studies)
- No need for suture removal
- Low cost
- Reduces risk of needlestick injury
- Hair apposition technique allows treatment of scalp wounds without shaving, with less pain, and much more quickly than traditional techniques

#### **DISADVANTAGES**

- Bond reaches strength equivalent to naturally healed tissue at 7 days after repair.
- Early dehiscence is the most common complaint. Wound strength on the first day is significantly less than with suture.
- Glue is very liquid, and inadvertent spillage or excessive application can cause adherence to gloves or other tissues as well as pain from heat of exothermic reaction.
- Dermabond, LiquiBand, and SurgiSeal are available as single-use applicators at typically double or triple the cost of a single pack of nylon suture.

# **EOUIPMENT**

- Dermabond single-use vials (Fig. 37-1A) or alternative brands. May find information on specific brands and their applicators at corporate websites: www.liquiband.com, www.adhezion.com (for SurgiSeal).
- Gloves.
- Single-use tissue approximators (Bionix Development Corp., Toledo, Ohio), gauze, or forceps (see Fig. 37-3A) (optional).
- Super Glue remover (optional). Acetone (nail polish remover) is the active ingredient.

# PREPROCEDURE PATIENT PREPARATION

Obtain verbal informed consent for the procedure. Explain that the wound will be cleansed and prepared, possibly involving analgesia. Some children may need to be restrained. Explain the procedure and warn the patient there may be a slight sensation of heat or stinging.

# **TECHNIQUE**

See Figure 37-2.

- 1. Meticulous wound preparation is essential and may require topical or infiltrated anesthetics. Good hemostasis must be achieved before application.
- 2. The patient should be positioned so that the fluid glue does not run off the wound to other areas.

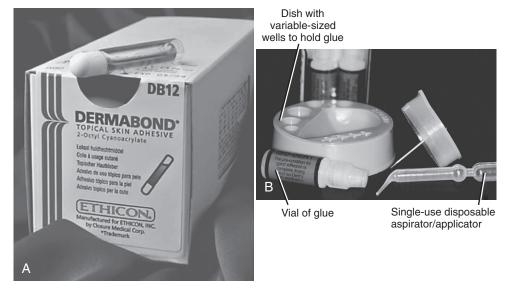

Figure 37-1 A, Dermabond single-use vials. B, Ellman IsoDent System. (A, Courtesy of Ethicon, Inc., Norwood, Mass. B, Courtesy of Ellman International, Inc., Hewlett, NY.)

- 3. The edges of the laceration are manually apposed. Clean, not sterile, gloves are acceptable for use, provided the wound is not inadvertently contaminated. For better traction, gauze, forceps, or disposable plastic tissue approximators may be used (Fig. 37-3).
- 4. The vial is crushed to start the flow of glue, and the glue touched to the wound edges. Dermabond and LiquiBand both have "chisel-tip" applicators, which purportedly improve accuracy. SurgiSeal has a sponge-tipped applicator.
- 5. The glue is gently painted over the wound. Care should be taken to keep the glue from entering into the wound, which can impair healing and precipitate a foreign body reaction. If there is doubt that the tissue edges can be reapproximated completely and evenly, suturing or stapling should be considered.
- 6. Apply only a few drops at a time. Heat is produced proportionately to the amount of adhesive applied and can be exquisitely painful. By the time the patient is feeling heat, it may be too late to wipe off the excess. Err on the side of caution.
- 7. The glue should be applied in an ovoid area (the wound being central) for best adhesive strength.
- 8. The manufacturer recommends a minimum of three separate coats. Each layer should be allowed to dry. The first will dry in

- about  $2\frac{1}{2}$  minutes. The surface, when dry, looks slightly rougher and more undulant than when it is wet. Subsequent layers dry more rapidly. Excess adhesive must be wiped off within 10 seconds.
- Steri-Strips, applied after drying, can help prevent wound dehiscence.
- 10. Hair apposition technique (HAT) for scalp lesions:
  - Twist together one or two hairs from each side of scalp laceration.
  - Apply a few drops of glue to the hairs.
  - Repeat every few millimeters along the laceration until it is completely approximated.
  - Caution patient not to wash hair for 2 days or vigorously brush or comb around the area of the laceration.

#### POSTPROCEDURE PATIENT EDUCATION

The adhesive is water resistant, and further dressing is not needed. The patient may wet the area but should pat it dry. Soaking is not recommended. Antibiotic ointment should be avoided because it will weaken the bond and dissolve the glue. A bandage may be appropriate for active people, children, or those inclined to pick or pull at the wound. The adhesive spontaneously sloughs in 5 to 14 days.

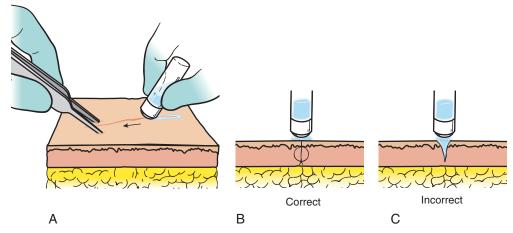

Figure 37-2 A, Approximate margins and apply glue. B, Correct application. C, Incorrect application into the wound itself.

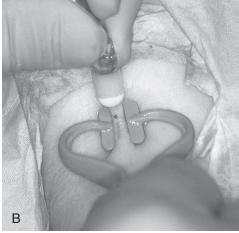

Figure 37-3 A, Plastic tissue approximators for the application of tissue glue. B, Application of tissue glue with the aid of plastic approximators.

Infections are unusual but can be detected early because the wound is visible and purulent exudate normally "unroofs" the adhesive. In these cases, the adhesive should be gently removed and standard wound infection treatment, possibly including systemic antibiotics, implemented. Reclosure with cyanoacrylate is not recommended.

# **COMPLICATIONS**

- Early wound dehiscence.
- If the practitioner's instruments, gauze, or gloves accidentally
  adhere to the wound or patient, pressure is placed adjacent to the
  area and the object is "rolled off" in a way that does not place
  traction on the repair.
- Adhesive that inadvertently binds the eyelids should be covered
  with generous amounts of ophthalmic antibiotic ointment and
  not pried open. The bond usually weakens and separates—if not
  immediately, then in 1 or 2 days. Cyanoacrylates are not harmful
  to the eye and are used routinely in ophthalmologic practice.
  Appropriate placement of gauze during repairs can prevent spillage into the eyes.
- Petroleum jelly, antibiotic ointment, or a commercially available
   Super Glue remover can be used on dried runoff areas.
- Adhesive may insinuate itself between wound edges, resulting in unacceptable healing.

# **PATIENT EDUCATION GUIDES**

See the sample patient education handout available online at www. expertconsult.com.

#### **COST**

Updated in 2010, Dermabond is about \$21 per *single-use* vial and comes in boxes of 12. Applying tissue glues conserves physician time, which is also a factor. Many institutions and offices are also now allowing other assistants to apply the adhesive.

# **CPT/BILLING CODES**

See Chapter 22, Laceration and Incision Repair, Table 22-4, for wound closure codes. The same codes are used whether the repair is performed with suture or with tissue glue.

#### **ICD-9-CM DIAGNOSTIC CODES**

ICD-9 codes for wound or laceration vary by location, degree, depth, and tendon involvement. See also Chapter 22, Laceration and Incision Repair.

#### **ACKNOWLEDGMENT**

The editors wish to recognize the contributions of J. Mark Wiedemanm, MD, and John L. Pfenninger, MD, to this chapter in the previous edition of this text.

# HYPERTROPHIC SCARS AND KELOIDS

Harris Mones • Dennis LaRavia

The skin of predisposed individuals may respond to injury or surgery by developing excessive growths known as *hypertrophic scars* or keloids. *Hypertrophic scars* are self-limited growths that enlarge within the boundaries of a wound and then often regress over time. Many hypertrophic scars spontaneously involute within 2 years. *Keloids* are benign, hard, fibrous proliferations of collagen that expand, either slowly or rapidly, beyond the original size and shape of a wound. They tend to persist and often invade surrounding tissue. They may become painful or pruritic as well as unsightly.

Hypertrophic scars and keloids represent abnormalities in the synthesis and degradation of collagen and extracellular matrix components. Hypertrophic scars have a 3-fold increase in collagen synthesis enzymes compared with normal scars, whereas keloids may exhibit 20 times the normal levels. Hypertrophic scars can occur at any site of skin injury. Those following surgical incisions usually remain linear. Burns frequently produce unsightly, pink, hypertrophic scars that may contract. The scars may itch, but generally they do not produce the pain and hyperesthesia seen with keloids.

The most important risk factor for keloid formation is a wound healing by secondary intention. This is especially true if wound healing time is greater than 3 weeks. Although most cases of keloids are sporadic, some cases are familial. In familial cases the mode of inheritance is unknown.

The incidence of keloids in dark-skinned individuals is 15 to 20 times that found in light-skinned people, and is higher in Asians. Overall, there is an equal incidence of lesions in males and females, although young females have a higher incidence than young males. Hypertrophic scars and keloids are found only in humans, occur in 5% to 15% of wounds, and are rarely seen in people older than 65 years of age. Keloids appear frequently in anatomic sites that are subject to motion, that overlie bony prominences, or are areas of increased skin tension or recurrent stretch, such as the shoulders, upper back, and presternal areas. Keloids may develop on the face and scalp after acne, or on the earlobe after ear piercing. They are seen more frequently in wounds that cross skin lines. Children and pregnant women are more likely to experience both hypertrophic scars and keloids.

This chapter focuses on office techniques used in the treatment of hypertrophic scars and keloids. Because of the natural regression of hypertrophic scars, therapy for these lesions is usually limited to topical application or injection of steroids and compression. Keloids are considered by some clinicians to be low-grade, benign, cutaneous tumors, and radiation therapy has been advocated. This therapy is not reviewed here. The malignancy potential of radiation in the treatment of a benign disease as well as its expense make radiation therapy a last resort. No single therapy for keloids has proven experimentally superior. Location, size, and duration are factors in choosing the most appropriate therapy. Cryotherapy, corticosteroid injection, surgical excision, pressure therapy, and irradiation—or a

combination of these modalities—may be chosen for the treatment of keloids.

#### **PREVENTION**

The most important thing to consider in the management of keloid scar formation is prevention. Before surgical procedures are performed, a thorough history of abnormal scar formation or a family history of keloid scar formation should be obtained from the patient. If a history of keloid formation is obtained, all nonessential surgery should be avoided, especially at sites that are at high risk. In circumstances where surgery cannot be avoided, all attempts must be made to minimize skin tension and secondary infection. Antibiotics, meticulous sterile technique, and, rarely, perioperative steroid injections (mixed with lidocaine) are helpful in prevention as well.

#### **CRYOTHERAPY**

Tissue destruction techniques used for treating keloids can incite further keloid formation. Cryotherapy, however, has been used with good results in 65% to 75% of cases. Both liquid nitrogen and nitrous oxide methods can be efficacious (see Chapter 14, Cryosurgery, Fig. 14-4). The more recent the keloid, the better the response to cryotherapy. A 10- to 15-second freeze with liquid nitrogen (-189° C) is usually required for keloids on most sites other than the mid-sternal region (small scars will take less time). Freezing for more than 10 to 15 seconds with liquid nitrogen can produce persistent post-treatment hypopigmentation. A 30- to 45-second freeze is usually adequate for most keloids when nitrous oxide (-89° C) is used. A better guide for any modality is to continue the freeze until 1 to 2 mm of normal tissue is involved and the complete thaw time is 1.5 to 2 minutes. During each treatment visit, the entire lesion must be treated with two to three freeze/thaw cycles.

After cryotherapy (see Chapter 14, Cryosurgery, Fig. 14-4), tissue edema will develop in 20 to 60 minutes. Within hours a significant bulla (blister) will appear. A rather copious serous discharge may follow. A moist environment (semiocclusive dressing) will aid healing. In southern and temperate climate areas, particularly during the summer months, occlusive therapy may prolong healing and increases the likelihood of secondary infection. Depending on the size of the lesion, five to eight treatments may be needed at 6-week intervals. Start conservatively and increase the freeze times if there are no untoward adverse effects.

Cryotherapy can also be used to soften hard keloids immediately before injection of steroids. Edema of the skin allows better dispersal of the steroid and minimizes its deposition into the subcutaneous or surrounding normal tissue. Cryotherapy before

injection (liquid nitrogen spray for 3- to 5-second burst[s]) may also improve keloid regression, allows for lower injection pressures, and decreases the pain associated with injections. Allow 20 to 60 minutes for the edema to develop before proceeding with the injection.

# **CORTICOSTEROID INJECTIONS**

Once a scar is palpable, topical corticosteroids, even under occlusion (e.g., flurandrenolide [Cordran] tape), are rarely beneficial. Raised hypertrophic scars and keloids, however, may be softened and flattened by intralesional corticosteroid therapy. Corticosteroids represent effective monotherapy for some hypertrophic scars and small keloids, and they are frequently used as the initial therapy for large keloids.

Early, small, or narrow lesions are initially treated with intralesional injection every 4 to 6 weeks. Early keloids are softer and more responsive to injection than older, inactive lesions. Avoid injecting into surrounding normal skin to prevent perilesional subcutaneous atrophy and telangiectasis formation. When a lesion flattens to nearly the level of the skin surface, allow more time to pass before injecting again and decrease the concentration of the injections. Overaggressive therapy can lead to hypopigmentation and a depression resulting from the atrophy.

Injections are frequently performed with a 27- or 30-gauge needle on a Luer-Lok syringe. Locked syringes help to prevent needle disengagement when injecting under pressure. Consider using cryotherapy immediately beforehand (see the previous section) to ease injection and spread of the steroid.

Many steroid regimens have been developed, and there is considerable variation in guidelines and recommendations for dosages and drugs. No clear advantage has been shown for any one type of corticosteroid. Triamcinolone acetonide 10 mg/mL (Kenalog-10) is a popular choice because of its 4- to 6-week duration of action. Although undiluted steroid can be used for unresponsive or dense lesions, it is more prudent to dilute the triamcinolone 1:3 with physiologic saline or 1% lidocaine (singledose vials) to create a 2.5 mg/mL solution. This dilute concentration limits postiniection hypopigmentation and atrophy. Injecting only lidocaine around the lesion using a 27- to 31-gauge needle before steroid injection improves patient comfort. Once the individual patient response is known, the concentration of triamcinolone acetonide can be increased to a dilution of 1:2 or 1:1 with lidocaine if necessary for future injections to increase the effect. If little effect is seen even without dilution, triamcinolone 40 mg/kg can be used and diluted as indicated. A common error is to be too aggressive. Go slowly to avoid the complication of atrophy. Hyaluronidase can be added to the solution to help disperse the steroid.

Administer the corticosteroid as the needle passes through the lesion. Keep the bevel of the needle pointed down. The scar may blanch temporarily with the injection. Try to keep the injection within the confines of the lesion to prevent side effects in the adjacent tissue. Firm lesions may limit the amount of medication that can be administered. The total amount will vary significantly depending on the size of the lesion. Keloids over 1 to 1.5 cm in diameter generally do not resolve as quickly or completely as smaller keloids. When the lesion is too dense to inject, consider treating with cryotherapy first, as previously discussed.

Another method of injecting steroids is to use the MadaJet Injector (see Pearl no. 8 in Appendix H, Pearls of Practice). The same concentration is used. The spring-loaded "gun" fires (dispenses) the solution, which is under pressure, into the lesion. No needles are involved, and there is less pain. Injections may again need to be repeated every 4 to 6 weeks to gain maximum benefit. The same dilutions are used.

Systemic effects from the corticosteroids are rare, but are possible with repeated injections of higher concentrations. Local effects include hypopigmentation, hyperpigmentation, perilesional atrophy,

perilymphatic linear atrophy, and local telangiectasia. These effects often improve over time. This therapy is generally considered safe and effective.

#### **SURGICAL EXCISION**

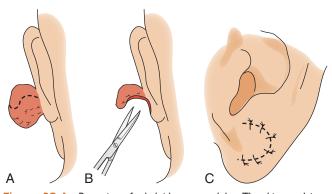

Therapy of keloids limited to traditional surgical excision with primary closure leads to a recurrence rate of greater than 50%. Mixing corticosteroids with the local anesthetic at the time of surgical removal provides superior results. In treating recalcitrant keloids over 1 to 1.5 cm, the best surgical results have been obtained using intralesional corticosteroid injections of triamcinolone (diluted to 2.5 to 5.0 mg/mL) into the immediate subcutaneous interface of the keloid and normal deep skin structures. The steroid injections can be administered 3 months and 6 weeks before scheduled surgical excision and again on the day of skin surgery immediately before the procedure. Follow-up at 4 and 8 weeks after surgery is important to detect any recurrence, which can be aborted with further injections. For smaller lesions, many clinicians will just inject at the time of surgery.

Proper surgical technique during the excision reduces the recurrence of keloids. Because tissue trauma may incite excessive growth, the wound bed and surrounding tissues must be handled gently. Avoid the use of instruments that crush tissue as well as overly aggressive cautery. Superpulse carbon dioxide lasers allow precise excision and cautery and cause minimal thermal damage to surrounding tissue. This makes them useful in excising some keloids, despite their relative expense. Radiofrequency surgery has similar results (see Chapter 30, Radiofrequency Surgery [Modern Electrosurgery]).

When an excision is performed, close the skin under minimal tension. Consider gentle undermining to decrease wound tension. Some surgeons avoid subcuticular absorbable sutures, which may increase tissue reaction. Skin closure should be accomplished with a very fine nonabsorbable suture material, such as 6-0 nylon. Topical adhesives ("tissue glues" such as Dermabond or IsoDent) and wound closure strips help close the wound with the least possible trauma and reduce tension on wound edges. They may also reduce the total number of sutures needed.

Some surgeons advocate removal of every vestige of a keloid; however, wide excision of normal skin around keloids does not reduce the rate of recurrence. Other surgeons advocate leaving a rim of incompletely excised keloid in place to serve as a barrier to further keloid growth. It is unclear whether this technique provides significant benefit over standard excisions.

Local advancement flaps can be used to limit the wound tension after excision. Figure 38-1 shows a low-tension flap created after the

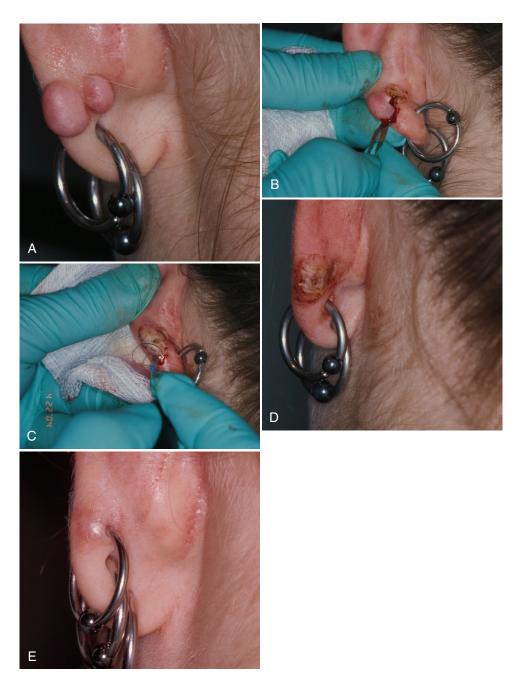

**Figure 38-1** Resection of a keloid on an earlobe. The skin overlying a keloid can be used to create a low-tension wound closure. **A**, Half the skin is selected for the flap. **B**, The skin is sharply dissected from the underlying keloid, and the subcutaneous keloid is totally excised. **C**, The wound is closed with simple, interrupted, nonabsorbable 6-0 nylon suture.

removal of a globular earlobe keloid. Although some practitioners advocate skin grafting to provide low-tension skin closure, large donor site keloids can also develop. Advanced closure techniques such as rotation advancement or M-plasty to cover large areas of keloid removal may be indicated to minimize tension on skin edge closure.

Evidence suggests using Silastic–silicone preparations (e.g., Mederma, ReJuveness, Biodermis, Mepiform, Kelokote) immediately after surgery may reduce the occurrence of keloids in those prone to excessive scarring.

A final surgical method of removing keloids is radiofrequency surgery. The large loop is used on a pure cutting setting. After anesthesia (with a dilute steroid included) the keloid is shaved off, followed by radiofrequency surgery/smoothing (Fig. 38-2).

Before attempting surgical excision of keloids, counsel the patient well. Patients with current or previous hypertrophic scars or keloids are more likely to form these types of scars after most surgical procedures, including dermabrasion. However, sculpting hypertrophic scars with traditional dermabrasion or carbon dioxide laser is usually beneficial and generally does not lead to recurrence of hypertrophic scars. It is more common in cases that are complicated by other factors, such as previous isotretinoin therapy, infection, or patient noncompliance with postoperative therapy. A detailed informed consent is useful in creating appropriate patient expectations. Photographs can be helpful before the procedure, immediately after the procedure, 3 months after the procedure, and 1 year after the procedure.

**Figure 38-2** Removal of earlobe keloid using radiofrequency technique. **A,** Keloid. **B,** Shave removal of lesion after local anesthesia, including low-dose steroid. **C,** Radiofrequency smoothing of wound base, using pure cutting setting. **D,** Appearance of wound on completion of procedure. **E,** Appearance I month later. Unfortunately, patient has repierced the area!

Postoperative results vary widely, and patients must understand that keloids may recur regardless of the treatment methods used. Warn patients that pigment variations may take several months after surgery to resolve. Sunscreens are essential. Patients should be seen at monthly intervals to identify any recurrence, and steroid injections or silicone treatments should be initiated or reintroduced early before the lesion becomes mature and large. It is recommended that patients should agree to surveillance of the wound closure site at least every 3 months for 1 to 2 years to ensure early intervention with postoperative intralesional corticosteroid injection if there is evidence of return of the keloid.

#### PRESSURE THERAPY

Pressure applied to burn sites can prevent hypertrophic scar formation or induce regression of early hypertrophic scars. Similarly, pressure dressings and garments after keloid surgery reduce their rate of recurrence. Pressure bandaging is used until the scar is no longer red; however, patient compliance may be poor when months or years of therapy are required. Many physicians prefer to use postoperative injections to ensure adequate therapy. However, when wounds are large or numerous, fitted pressure garments may be the best alternative.

After earlobe keloid excision, a pressure earring can be worn as soon as the skin sutures are removed (usually 5 to 7 days). A spring-loaded, light-pressure earring prevents the complication of skin necrosis. Hypoallergenic pressure earrings with a self-adjusting clasp are available from Padgett Instruments (Kansas City, Mo; 1-800-842-1029) and many other medical supply companies. These earrings cost about \$40 and are available in a variety of styles and colors that encourage prolonged use. A less expensive alternative is to use large, flat, back-clip earrings lined with Silastic sheeting cut to fit inside them. Silastic sheeting alone has been therapeutic in reducing keloids and hypertrophic scars but is best combined with repetitive intralesional steroid injections and compression to hold it in place.

# **LIGHT THERAPY (LASER AND OTHERS)**

Continuous-wave carbon dioxide laser used in the cutting mode has been shown to be effective for some refractory keloids. All possible keloid tissue is excised with the laser, and the wound is allowed to heal by secondary intention or is closed with minimal tension, as noted previously. Concurrent intralesional steroids, compression dressings, or silicone treatments may be helpful. Depending on the size, depth, and location of the wound, as well as the patient's health, healing may take as long as 3 months. Transient hypertrophic scars develop in up to 30% of cases; unfortunately, as with other treatments, recurrence rates are high. Superpulse carbon dioxide laser may prove to be better, but long-term studies are pending. Flashlamp-pumped pulsed-dye lasers (585 nm) and intense pulsedlight lasers (e.g., PhotoDerm) are used to treat relatively flat hypertrophic scars and keloids. The advantage of using lasers relates to the precision with which the light energy can be delivered to the target rather than the surrounding tissue and the absorption of specific wavelengths of light by the vascular components of the target. Multiple sessions are required and cost may be a factor for some patients, but results are frequently impressive.

#### **ALTERNATIVE METHODS**

Some investigators inject hyaluronidase with steroids after cryotherapy, with improved results. Others have applied Imiquimod 5% cream (Aldara) postoperatively to help prevent keloid recurrence after surgical excision. The cream is applied postoperatively on alternate nights for eight weeks. Although their mechanism of action is unknown, topical silicone gel and silicone sheeting are used with success. The gel's impermeability to water is thought to mini-

mize evaporation and provides a semiocclusive dressing that accelerates healing and shortens the inflammatory phase. Topical Silastic gels and Mederma gel (a vegetable oil extract) have proved to be beneficial in reducing both volume and redness of lesions. The silicone sheets (e.g., Mederma, ReJuveness, Biodermis, Mepiform, Kelokote) must be worn 12 to 24 hours per day for 3 months or more. They are applied under tape or a pressure garment. The sheet is 3.5 mm thick and is applied over the scar only. It is held in place with paper tape and removed and washed daily. Its effect is unrelated to pressure. Perioperative injection with interferon has been used. One study of 12 patients showed a recurrence rate of less than 10% after traditional excision, interferon injection, and follow-up of nearly 15 months. Intralesional bleomycin has also been tried with some success. 5-Fluorouracil 50 mg/mL mixed with triamcinolone 1 mg/mL injected one to three times weekly into hypertrophic scars may be efficacious in decreasing scar tissue. Verapamil, cyclosporine, D-penicillamine, relaxin, topical mitomycin C, Cordran tape, and tacrolimus are other options that have been studied.

## **CONCLUSION**

Stepwise treatment as well as combination of modalities may prove to be the most effective manner to treat keloids. If initial topical (or injected, high-potency) steroids and compression do not resolve the lesion, cryotherapy may soften the lesion and allow improved injectability. Next, excision or careful vaporization of the bulk of a lesion with carbon dioxide superpulse laser may be indicated. If resection is attempted, careful, low-tension closure with minimal sutures or healing by secondary intention is recommended. Excision followed by several sessions of 500- to 600-nm pulsed light or laser or low-dose radiation is also an option. Application of topical gels and pressure dressings combined with various modalities seems to produce acceptable results even with difficult lesions.

# **CPT/BILLING CODES**

There are no specific codes for treatment or excision of hypertrophic scars or keloids.

11900 Intralesional injection up to and including 7

11901 Intralesional injection more than 7

Also include the J code and amount for substance used.

# **ICD-9-CM DIAGNOSTIC CODE**

701.4 Keloid or scar

## **ACKNOWLEDGMENT**

# EPILATION OF ISOLATED HAIRS (INCLUDING TRICHIASIS)

Kathleen M. O'Hanlon

The method used to permanently remove problem hairs, such as misdirected eyelashes or ingrown hairs, depends on the anatomic location of the hair and the condition of the surrounding skin. The simplest approach, typically used by electrologists, applies electrical current to cause follicular destruction. In radiofrequency surgery, household current is converted to a frequency of 3.9 MHz, resulting in heating and vaporization of water in the tissue and subsequent destruction of the hair root. This process results in minimal lateral heat transfer, allowing for selective ablation of lash follicles without the side effects on the lid previously experienced with electrocautery (see Complications). In the presence of inflammatory disease with ingrown hairs, a more comprehensive skin care program should be used first to decrease the density of papules and pustules. For removal of large areas of hair, new laser applications have been developed. The units are expensive but time saving and effective (see Chapter 48, Lasers and Pulsed-Light Devices: Hair Removal).

# **PHYSIOLOGY**

Hair is formed by the replication of cells in hair follicles. The growth phase (anagen) commences with germinal papillae descending into the dermis. This is followed by cellular proliferation (catagen), during which a bulb and a hair are formed. Once growth has ceased, the follicle shrinks and enters into the resting phase (telogen). The duration of each phase of the cycle depends on the type and location of the hair. Short hairs, such as human eyelashes, spend the majority of their time in the telogen phase, during which the germinal cells reside near the base of the follicle. Hair ablative procedures therefore need to apply heat energy (electrolysis or radiosurgery) specifically to the base of these follicles.

# **Trichiasis**

Abnormal eyelashes may be congenital or may result from trauma, infections, diseases such as Stevens-Johnson syndrome, chronic disease, and allergies, medication use, or even the aging process. Cilia inversum is a rare finding in which a lash originates in the tarsal conjunctiva instead of anterior to the tarsal plate. Cilia incarnata, an anomaly akin to ingrown hair, develops when a lash is trapped beneath the skin near the lid margin. In distichiasis, lashes grow from the meibomian gland orifices posterior to the normal lashes. True trichiasis, an acquired condition in which one or more lashes is misdirected posteriorly toward the conjunctiva or cornea, may pose a range of problems, from irritation to corneal abrasion or ulceration. Localized hairs may be suitable for tweezing, followed by permanent ablation if they recur. On the upper lid, the eyelash bulb has been determined to be about 2.4 mm below the surface of the lid margin, and the lower lid follicles are about 1.4 mm deep. Lanugo hairs or widespread trichiasis may require more specialized surgical procedures and should be referred to an ophthalmologist.

# **Ingrown Hairs**

Ingrown hairs, *pili incarnati*, originate from a variety of causes. Razorshaved hair ends have very sharp tips that may curve back toward the skin surface and reenter the epidermis a short distance from the mouth of the follicle (common in black people or people with curly hair). Double-edged razors, in which the hair is pulled out of the follicle by the first razor and cut by the second razor, leave the resultant hair tip recoiled in the follicle below the surface of the skin. The curved hair may then grow into the follicular wall. As the hair tips pierce the epidermis or penetrate the dermis, a foreign body inflammatory reaction ensues. Usually the ingrown hairs are completely buried, but they may have an identifiable recurving loop. In treating such hairs, the unattached end of the hair must be exposed above the surface of the skin using sharp forceps. Impacted hairs, which cannot be freed, should be left in place until a subsequent visit.

#### **INDICATIONS**

- Trichiasis
- Ingrown hairs (e.g., pseudofolliculitis barbae and other related disorders)

#### **RELATIVE CONTRAINDICATIONS**

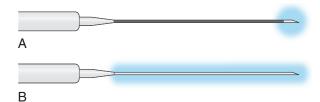

- History of recurrent herpes (premedicate before epilation)
- Inflammatory skin condition (controlled)
- "Demand" cardiac pacemaker (radiofrequency wave can cause pacemaker malfunction, resulting in palpitations or even asystole)

#### **ABSOLUTE CONTRAINDICATION**

Active herpetic outbreak

# **EQUIPMENT**

- Radiosurgery unit (Surgitron; Ellman International, Hewlett, NY).
- Ellman's "insulated needle electrode" (catalog no. D6) or flexible probes (fine wires or 33-gauge needles) may be necessary for the curvaceous ingrown hairs (Fig. 39-1).
- Small tweezers.
- Alcohol wipe.
- Loupes or magnification lamp (optional—but very helpful).
- Topical anesthetic (*optional*; e.g., EMLA, ELA-Max, Hurricaine Gel; see Chapter 10, Topical Anesthesia).

**Figure 39-1** Two common needles used for epilation. **A,** Coated with only the tip active. **B,** Uncoated with entire needle active. (Courtesy of Ellman International, Hewlett, NY.)

### **PRECAUTIONS**

- Excess insertion depth of epilation needle can cause unnecessary scarring.
- Power set too high can result in lid or corneal side effects, including scarring.
- In the case of the ingrown hair, the shaft should be pulled gently to indicate the direction of the follicle, and a preferably *flexible* probe should be inserted for epilation. Probes that do not conform to the curvature of the hair may not reach the hair root. Although rare, incomplete electrolysis may create an ingrown hair if a distorted follicle is sealed off by the current.

# PREPROCEDURE PATIENT EDUCATION AND FORMS

See patient education, encounter, and consent forms online at www. expertconsult.com.

#### **PROCEDURE**

See Figure 39-2.

- Prepare area with alcohol.
- Apply topical anesthetic (optional).
- Set the Ellman Surgitron to 10 W or less (level 1) in the coagulation mode.
- Place the insulated needle electrode into the handpiece. Alternatively, use the 33-gauge needle and a needle hub adapter.

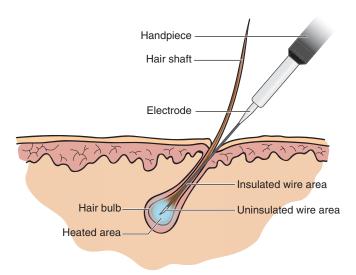

Figure 39-2 Using a fine needle electrode for epilation. (Courtesy of Ellman International, Hewlett, NY.)

- Identify the exposed end of the hair and, pulling the shaft gently with tweezers, insert the needle into the follicle until resistance is met, and activate the unit.
- Remove the hair with tweezers. It should come out easily.

#### SAMPLE OPERATIVE REPORT

See sample operative report online at www.expertconsult.com.

#### COMMON ERRORS

- Inadequate penetration depth, resulting in unsuccessful permanent ablation
- Excessive cautery to the tissue

# **COMPLICATIONS**

Although extremely rare, the following are potential complications:

- Recurrence of hair growth ("permanent" ablation is not 100% effective)
- Eyelid complications, including cellulitis, hypopigmentation or hyperpigmentation, lid deformities (e.g., notching, scarring much more likely with *electrocautery*, which is not recommended by the author)
- Cicatricial conjunctival disease due to heat damage (also more likely with electrocautery)
- Potential hazard to the globe (due to close proximity)
- Activation of herpes zoster

#### POSTPROCEDURE MANAGEMENT

Antibiotic (eye) ointment for 3 to 5 days or until localized pits have granulated.

## POSTPROCEDURE PATIENT EDUCATION

See patient education form online at www.expertconsult.com.

#### **CPT/BILLING CODES**

- 17380 Electrolysis epilation; each ½ hour
- 67820 Correction of trichiasis; epilation by forceps only
- 67825 Correction of trichiasis epilation by electrosurgery, cryosurgery, or laser

# **ICD-9-CM DIAGNOSTIC CODES**

- 374.00 Entropion
- 374.05 Trichiasis w/o entropion
- 374.54 Hypertrichosis of eyelid
- 704.1 Hirsutism/hypertrichosis (excessive growth of hair)
- 704.2 Trichiasis

# TOPICAL HEMOSTATIC AGENTS

Dale A. Patterson • Matt D. Roth

In medical training there is a cynical phrase quoted to novice medical students on a surgery rotation: "All bleeding stops eventually." Although this is true, the lesson to learn is that usually the best amount of bleeding is the least amount of bleeding. Effective, rapid hemostasis is the goal of physicians performing cutaneous surgery. This chapter covers the most useful methods of achieving topical hemostasis (Table 40-1).

The various methods range from physical techniques, such as simple pressure with an index finger and gauze pad, to chemical, electrical, and even laser techniques. The method used depends on the specifics of the surgery being performed, the experience of the office surgeon, and the availability of the agents or equipment.

Each method has its own benefits and drawbacks, and the astute clinician will match the method that best fits the needs of the particular patient. The older chemical agents (the so-called vasoconstrictive, vaso-occlusive, or denaturing agents) produce an eschar and actually cause some tissue damage. Newer, so-called physiologic agents facilitate the clotting mechanism but can be exorbitantly expensive (e.g., \$30 or more for a single pack of Gelfoam). It is therefore important for the physician or health care provider to be familiar and accomplished with multiple methods to ensure the most positive outcome.

# **INDICATIONS**

- For the treatment of
  - Bleeding after cutaneous surgery such as a shave biopsy
  - Abrasions or denuded skin
  - The nail bed after removal of either partial or full nail
  - Cuts or open wounds that cannot or will not be primarily closed
- To cauterize excess granulation tissue

## **CONTRAINDICATIONS**

#### **Absolute**

- Profuse bleeding. Topical agents will not control briskly bleeding vessels.
- Allergy to the hemostatic agent used.

# **Relative**

- Large, deep wounds that require primary surgical closure with suture (use mechanical methods only).
- Cardiac pacemaker may preclude use of electrosurgery (e.g., Bovie, Hyfrecator).

**NOTE:** Cautery technically refers to a hot wire (most often, a battery-powered unit). This method is generally safe for patients with a pacemaker. On the other hand, *electrocautery* (e.g., Bovie, Hyfrecator, Ellman Surgitron) produces a low-amperage current (causing electrofulguration, electrodesiccation, or electrocoagulation) that

may pose a risk to pacemaker users. Most new pacemakers are shielded. Use of these electrosurgical units should not be a problem, but other safe alternatives exist. See Chapter 30, Radiofrequency Surgery (Modern Electrosurgery), for details of electrosurgical principles.

# **EQUIPMENT AND SUPPLIES**

# **Hemostatic Agents**

See Figure 40-1 for a depiction of several common hemostatic agents.

## **Vaso-occlusive Denaturing Agents**

#### Most commonly used

- Ferric subsulfate solution (20%; Monsel's solution)
- Aluminum chloride (30% solution; Drysol)
- Silver nitrate sticks or 20% to 50% solution
- Hydrophilic polymer and potassium salt (QR powder)

#### Not recommended

- Trichloroacetic acid (50% to 85% solution)
- Zinc chloride paste
- Phenol 50% solution
- Hydrogen peroxide 3% solution

# Agents Producing a Physical Meshwork

- Absorbable gelatin sponge (Gelfoam)
- Oxidized cellulose (Surgicel)
- Microfibrillar collagen (Avitene)
- Cyanoacrylates (Dermabond, IsoDent; see Chapter 37, Tissue Glues)

# Physiologic Hemostatic Agents

- Epinephrine, or lidocaine with epinephrine
- Thrombin (Thrombostat)
- Fibrin sealant
- Cocaine hydrochloride solution

#### **Combination Products**

- Flowable bovine collagen and bovine platelets (CoStasis)
- Flowable bovine gelatin matrix and bovine thrombin (FloSeal)

#### Agents for Traumatic Injuries

- QuikClot (granular zeolite powder)
- HemCon (Chitosan dressing)
- ChitoFlex (Chitosan dressing)

## **Mechanical Methods**

- Electrocautery ("hot-wire," battery-operated unit)
- Electrosurgery (e.g., Bovie, Hyfrecator, Ellman Surgitron)

TABLE 40-1 Topical Hemostatic Agents					
Generic/Product Name	Effectiveness	Difficulty of Preparation/ Application	Undesired Tissue Destruction	Chance of Pigment Stain (Usually Temporary)	Cost
Vaso-occlusive/Denaturing Agent Recommended	:s

+ Easy to prepare/apply to +++++ Difficult to prepare/apply
Hinimal damage to +++++ Significant destruction
Low pigment stain to +++++ High chance of pigment stain

\$ Low cost to \$\$\$\$ High cost

- Indicates no effect.

- Laser (carbon dioxide)
- Shaw scalpel (a teflon-coated scalpel blade with a heating element)
- Application of ice
- Pressure dressings

# PREPROCEDURE PATIENT EDUCATION

Discuss the procedure, including the rare but possible risks of further bleeding, infection, nerve damage, and scarring. Determine if the patient is known to be allergic to any of the agents. If using silver nitrate or Monsel's solution, inform the patient of the possibility of pigmentary change ("tattooing"), which is usually temporary but still requires discretion when being used in exposed areas such as the face.

Figure 40-1 Common hemostatic agents. From top to bottom: silver nitrate stick, aluminum hydroxide with applicator, and absorbable Gelfoam.

# **PROCEDURE**

Please see the corresponding chapter for the initial procedure being performed. *Topical hemostatic agents* are not a substitute for meticulous surgical technique, and many *cannot* be used inside a wound to be sutured. When topical hemostatic agents are required, ensure the patient is positioned on the examination or procedure table to provide adequate access to the wound.

# **Vaso-occlusive Denaturing Agents**

These agents are applied topically and are *not* used if a wound is to be closed surgically. To maximize the coagulation effect, these agents should be applied as close to the source of bleeding as possible, and the wound should be sponged free of excess blood just before their application.

# Ferric Subsulfate Solution (20%; Monsel's Solution)

First described by Leon Monsel in 1856, this liquid is perhaps the most commonly used topical hemostatic agent (Fig. 40-2). The solution is dark brown, almost black. If the bottle is left open, evaporation results in a pasty solution that, because it is more concentrated, is more effective. Do not let it become too thick, however. If it crystallizes, it can be reconstituted with water. Keep the container covered once the desired consistency is obtained. Hemostasis is effective with only rare staining, which can last up to 3 months. Application of Monsel's solution to a relatively dry wound bed (achieved by stretching and blotting the skin) controls oozing effectively.

Monsel's solution is applied with a cotton-tipped swab after drying and stretching the skin with the other hand. The swab is applied with light pressure. The low pH and the subsulfate group denature protein and occlude blood vessels. The practitioner cannot

**Figure 40-2** Topical astringent. **A,** Monsel's solution in open bottle, which allows it to thicken. **B,** Inner bottle. **C,** Cotton-tipped applicator used to apply thickened solution. Do not reinsert into bottle/container. **D,** Applying Monsel's with cotton-tipped applicator.

use too much. Once in contact with blood, the black, coagulated mixture can be wiped away. Monsel's works particularly well after cervical biopsies, loop electrosurgical excision procedures, and anorectal biopsies. It is also commonly used after shave excision and punch biopsies except in very fair-skinned individuals.

Monsel's solution is inexpensive, easily applied, easily stored, and readily available. However, there is a rare risk of "tattooing," so some physicians do not recommend it for the face, especially on light skin (Fig. 40-3). In clinical practice there is often a compromise in which Monsel's, given its superior hemostatic properties, is still used for the face and on patients with a very light complexion. (Aluminum chloride is nonstaining and should be tried first in these cases.) The tattooing can last several months. Monsel's may also cause temporary artifactual changes in skin and cervical biopsies, confounding the histologic evaluation of reexcisions for a few weeks thereafter. It also stains clothing. Stains on laboratory coats can be removed with dilute hydrochloric acid, such as that often found in toilet bowl cleaners, or by using Iron-Out. Monsel's stains need to be treated

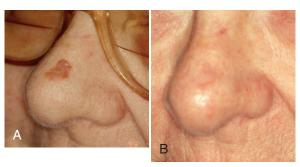

before washing in hot water or drying with heat because each seems to set the stain permanently.

# Aluminum Chloride (30%)

Aluminum chloride is usually applied topically to a wound as a 30% solution (e.g., Drysol, Lumicaine) on a swab with light pressure (Fig. 40-4). It is colorless and forms a thin coagulum over the wound. Although not as effective as Monsel's solution, it does not cause tattooing. This solution is commonly used after surgical shave biopsies.

# Silver Nitrate

Silver nitrate is available as a 20% to 50% solution and as a solid on a wooden stick. The sticks are more convenient and consequently more popular. The silver nitrate on the end is activated when the tip is placed on a moist wound bed. Silver ions cause proteins to precipitate, which occludes blood vessels. The eschar that forms in the wound bed prevents deeper tissue penetration

**Figure 40-3** Monsel's staining. **A,** Three weeks after initial use. **B,** Spontaneous resolution after 6 to 8 weeks.

Figure 40-4 Aluminum chloride (clear solution).

Figure 40-5 Shave biopsy partially cauterized by silver nitrate stick.

by the hemostatic agent. Silver salts stain the tissue black because of the deposition of reduced silver. Although most of the stain disappears spontaneously within a few weeks, there is a modest possibility of permanently tattooing the treated site. Care must be used with silver nitrate to avoid damaging normal tissue surrounding a wound. Because of these concerns, silver nitrate is most often restricted to cauterization of excess granulation tissue or for use in nonvisible areas (e.g., cervix, rectum). Figure 40-5 shows silver nitrate hemostasis of a shave biopsy.

# Trichloroacetic Acid (50% to 85%)

Trichloroacetic acid is a topically applied agent that also forms an eschar at the wound bed. When it touches the tissue, the acid also causes superficial tissue destruction, and subsequently is *rarely used* for hemostatic purposes and is *not* recommended. Without anesthesia it can be painful, so application should be precise and rapid.

# QR Powder (Hydrophilic Polymers and Potassium Salt)

This product is available over-the-counter and for professionals (Fig. 40-6). Blood must be present for it to work. The product is supplied

in an individual-use packet with a cost of about \$2 per packet. A thin coating of the powder is applied to the wound and pressure held for 15 to 60 seconds. Pressure is applied until bleeding stops (see Fig. 40-6D and E). If bleeding recurs, another application of the product can be made, even by the patient at home. The eschar should be left in place until it naturally "falls off." It is safe to wash and bathe the area 1 hour after application of the product. QR powder is not biologically derived and is not known to cause allergic reactions, tattooing, or discoloration of the skin. It can be used on any wound left to heal by secondary intention and has been successfully used to stop bleeding from the nose, abrasions, punctures, and minor surgical procedures. It should not be used below the surface of the skin on sutured wounds and is for topical/external use only. It does not cause pain or any pigment changes.

#### Other Agents

Zinc chloride paste is an effective hemostatic agent that was used in the original fixed-tissue Mohs' micrographic surgery, and it is still occasionally used today. Phenol 50% is effective, but the severe caustic effects on normal tissue may enlarge a wound. For this reason, it may be useful in nail removal for achieving hemostasis while providing destruction of the nail matrix. Hydrogen peroxide is readily available and is a weak hemostatic agent. It has obvious germicidal action, is inexpensive, and is easy to apply. Hydrogen peroxide is commonly applied directly to the wound in saturated gauze with direct pressure. It too causes some degree of tissue destruction and is rarely used for hemostasis alone.

# Agents Producing a Physical Meshwork

Surgical wound closure is acceptable after use of most of the following agents.

#### Absorbable Gelatin Sponge (Gelfoam)

Gelatin powder is applied dry to the wound bed with light pressure. Absorbable gelatin sponges are manufactured in various forms from purified gelatin solution. Gelatin sponges can be applied dry or moistened with saline or thrombin. Absorbable gelatin holds blood

**Figure 40-6** QR ("Quick Release") powder. **A,** Available in packets (*lower right*) or bottle dispensers. **B,** QR in use: applying from packet to shave excision. **C,** Appearance on wound before applying pressure. **D,** Applying pressure with a cotton-tipped applicator. **E,** Final appearance; hemostasis is obtained. A dressing is applied without antibiotic ointment.

and provides a matrix for clot formation and granulation tissue to form. The sponges are costly for a private office but are convenient and easy to handle. The gelatin powder can be difficult to handle and may be less effective than other meshwork agents.

Potential side effects include excessive granuloma formation and fibrosis. Care should be taken if these sponges are used near tendons because they have been known to cause excessive fibrosis especially in these areas.

#### Oxidized Cellulose (Surgicel)

Oxidized cellulose consists of absorbable fibers prepared from cellulose. Woven strips or sheets of cellulose can be cut and held with firm pressure on the wound bed. Oxidized cellulose provides a meshwork for coagulation and causes local vasoconstriction. This preparation is moderately priced, easy to handle, and mildly bactericidal.

Foreign body reaction is possible if excessive amounts of cellulose are left in a wound. Cellulose should not be used under grafts or flaps because it separates the graft from the blood supply. Some experts believe that the removal of oxidized cellulose after obtaining hemostasis frequently produces rebleeding.

#### Microfibrillar Collagen (Avitene)

Microfibrillar collagen is prepared by mechanically breaking down bovine collagen into fibrils. It is available in a fibrous (granular) form or a web form. The fibrous form is applied directly to the wound and held in place. The highly effective collagen products aggregate platelets on their surface. Collagen matrix applied to skin biopsy sites produces fewer infections, faster healing, and better cosmetic results than Monsel's solution.

Microfibrillar collagen adheres to wet gloves or surfaces, and it must be applied with dry instruments. Although the collagen is eventually absorbed, it cannot be used at skin closure sites because it impedes the healing of wound edges. The high cost and difficulty in handling make this agent impractical for most office dermatologic surgery.

#### Cyanoacrylates (Dermabond, IsoDent)

Tissue glues can seal wound edges and halt bleeding. See Chapter 37, Tissue Glues.

#### Physiologic Hemostatic Agents

#### **Epinephrine**

Epinephrine is a potent activator of adrenergic receptors, and the activation of  $\alpha$ -adrenergic receptors produces vasoconstriction in the skin. Epinephrine is available in local anesthetics such as lidocaine with epinephrine or as adrenaline chloride solutions. Epinephrine is inexpensive and readily available, and it does not harm normal tissue at the base of the wound. It can be applied topically to control bleeding (e.g., the nose) or injected into a bleeding site (e.g., cervical biopsy). Effects are temporary (about 2 hours). Control of the bleeding, however, allows electrocoagulation or application of other topical agents if necessary.

Complications are quite rare. The precaution is always to avoid its use in end-arterial areas (i.e., finger, nose, penis, toes) for fear of causing distal necrosis. This rarely occurs. However, caution is advised in the vascular-compromised patient. Rebound vasodilation can potentially cause delayed bleeding. Cardiac arrhythmias and neurologic symptoms have been reported with the use of epinephrine in dermatologic procedures.

#### Thrombin (Thrombostat)

Thrombin is a potent physiologic clotting agent produced by the activation of bovine prothrombin. This freeze-dried powder either can be mixed with isotonic saline and sponged or sprayed on the wound bed or can be applied directly as powder. The wound should

be sponged free of excess blood before thrombin is applied. For superficial surgery or plastic surgery involving flaps, dilute solutions of 100 units/mL may be effective.

Thrombin does not injure tissue or produce residue on the tissue bed. Once the solution is prepared, it must be used within 6 hours. Thrombin is expensive, prohibiting the routine use of this agent for office procedures.

#### Fibrin Sealant

Fibrin sealant is produced by making two components of human clotting factors immediately before application. Fibrin clot forms in about 30 seconds; the sealant can be applied with a special spraying device that mixes the components as they are delivered into the wound. Fibrin glue is one of the most effective agents available for hemostasis. The cost, the risk associated with the use of human blood products, and the cumbersome administration make this therapy undesirable for routine dermatologic surgery.

#### Cocaine Hydrochloride

Cocaine hydrochloride is useful as a powerful vasoconstrictor, but the potential for abuse, the cost, and the need for locked storage make its use problematic.

#### **Combination Products**

Combination products, such as CoStasis and FloSeal, use both meshwork and hemostatic agents in surgical procedures when conventional methods of hemostasis are unsuccessful. They are impractical for office procedures owing to their cost and limited applicability in routine procedures. A combination of a hydrophilic polymer and a potassium iron oxyacid salt, PRO QR powder, has more recently become available and is gaining popularity in office and emergency department settings.

#### **Agents for Traumatic Injuries**

#### OuikClot (Granular Zeolite Powder)

QuikClot has been approved by the U.S. Food and Drug Administration for the treatment of external hemorrhage. Much of the experience in the use of QuikClot has been in military applications. When applied to a wound, the granular zeolite powder attracts water and dries the wound in an exothermic reaction. This drying effect increases the rate at which red blood cells aggregate and decreases blood loss. The product has been shown to reduce hemorrhage from major traumatic wounds and has been used by the military in Iraq and Afghanistan. QuikClot is supplied in various forms, including sponges, bandages, granular packets, and nasal applicators. Each of these forms is applied directly to an external bleeding wound and combined with pressure to stop hemorrhage. The original product caused a significant temperature elevation in the surrounding tissue, but a reformulated product has been released that decreases the amount of heat released during application.

#### HemCon and ChitoFlex (Chitosan Dressings)

Chitosan is a mucoadhesive, biodegradable polysaccharide derived from shellfish. HemCon and ChitoFlex supply chitosan in ready-to-apply bandages. When exposed to blood, the bandages become extremely adherent and facilitate clotting. The molecule is also positively charged and may attract negatively charged erythrocytes, further enhancing clot formation. HemCon bandages are larger and supplied in various sizes to treat external wounds. ChitoFlex bandages are more flexible and compact, facilitating the treatment of penetrating trauma tracts. Both are latex free and have no known complications or contraindications. They can be left in place for up to 48 hours and should be removed with water or saline for definitive wound treatment.

#### **Mechanical Methods**

- Cautery (electrosurgical or battery-operated unit): For hemostasis, use the coagulation or fulguration settings and set at a very low power. Gently "tap" the area, being careful to avoid excessive tissue damage. Larger vessels (>3 mm) should be tied off rather than coagulated.
- Laser (carbon dioxide): Rarely used for this purpose.
- Shaw scalpel (a teflon-coated scalpel blade with a heating element).
- Ice packs: Cause vasoconstriction and reduce bleeding and swelling.
- Pressure dressings (see Chapter 32, Skin Biopsy, Fig. 32-8, for an example).

#### **COMMON ERRORS**

- Using agents capable of producing "tattooing" (Monsel's or silver nitrate) in a visible area on a light-skinned person. Choose an agent that does not have this risk.
- Overcauterizing an area of bleeding, leading to more tissue destruction than necessary. Use only the minimal amount of chemical, electric, or thermal cautery to stop the active bleeding.
- Using ferric subsulfate, aluminum chloride, or silver nitrate inside a wound that needs to be sutured closed.

#### **COMPLICATIONS**

- Rebound bleeding
- Infection
- Nerve damage
- Scarring or tattooing
- Swelling
- Excessive tissue damage

#### POSTPROCEDURE PATIENT INFORMATION

Instruct the patient on the following:

- Keep the area clean and moist, but avoid maceration. Any ointment, including those with antibiotics, aids healing.
- Change the dressing at least two to three times a day (preferably four) and wash gently with soap and water.
- Follow-up as directed; do so sooner if there is an increase in redness, swelling, pain, fever, night sweats or chills, or other signs of infection such as purulent drainage.
- Avoid cleansing with hydrogen peroxide because it kills fibroblasts.

#### **CONCLUSION**

Hemostatic agents are useful during cutaneous surgery or when faced with an open wound that cannot be primarily closed with sutures. Topical hemostatic agents are not a substitute for meticulous surgical technique, and many cannot be used inside a wound to be sutured. Physical measures such as direct pressure, cold application,

or suture ligatures should also be considered when trying to control bleeding. The various agents have benefits and limitations. It is important to become familiar with several, such as Monsel's solution, aluminum chloride, absorbable gelatin sponge (Gelfoam), and oxidized cellulose (Surgicel).

#### **BILLING AND CODING**

Application of topical hemostatics is included in the wound care charge and should not be "unbundled." If a patient presents with a condition requiring topical hemostasis, the appropriate level of service should be billed. ICD-9-CM codes are indicated for the particular lesion or presenting concern being addressed.

#### **ACKNOWLEDGMENT**

The editors wish to recognize the many contributions by Jerry W. Hizon, MD, and Lee A. Kaplan, MD, to this chapter in the previous edition of this text.

# Unna Paste Boot: Treatment of Venous Stasis Ulcers and Other Disorders

Paul W. Davis

#### **BACKGROUND**

Venous stasis leg ulcers are the most common type of ulcers on the lower extremities. They most often occur on the medial aspect of the ankle and can be either partial or full thickness. Their shape is usually irregular and there is often associated edema, skin hyperpigmentation, induration, and thickening of the dermis and epidermis. Plaquelike lesions, called *lipodermatosclerosis*, are frequently observed. Erythema may be present, especially when the feet are dependent. This remarkable redness can frequently cause the clinician to suspect the presence of cellulitis. These ulcers are often painful and are accompanied by a significant amount of exudative drainage, again suggesting cellulitis.

Leg ulcers affect an estimated 500,000 to 1 million people in the United States. One percent of people in industrialized countries will suffer from a leg ulcer at some point in their lives and the vast majority of these are secondary to venous problems. Venous leg ulcers are the end result of chronic venous insufficiency (CVI), which leads to venous hypertension, inadequate venous blood return, and increased capillary pressure in the lower extremities. Chronic and recurrent venous obstruction, progressive valvular damage, and impairment of the calf muscle pump are the root causes of CVI.

A variety of hypotheses have been proposed to explain the pathophysiology of venous ulceration. One theory is that *sluggish* venous flow leads to the adherence of leukocytes to the capillary walls, resulting in obstruction of the local capillaries and the migration of additional leukocytes into the surrounding subcutaneous tissue. Proteolytic enzymes and toxic metabolites are released, increasing capillary permeability and destruction. Local ischemia, tissue necrosis, and ulceration are the final result. The fibrin cuff theory suggests that increasing venous hypertension causes fibrinogen molecules to leak out of the damaged capillary endothelial cells, polymerizing to fibrin and forming thick deposits around the remaining capillaries. Thus, "fibrin cuffs" form, posing a barrier to diffusion of oxygen and nutrients throughout the tissues of the lower extremities and leading to fibrosis, necrosis, and ulceration.

The *trap hypothesis* incorporates the theories described previously and further suggests the extravasation of erythrocytes from the capillary bed. These "trapped" red blood cells are broken down in the tissues and release hemoglobin, which is metabolized to hemosiderin. This hemosiderin is responsible for the brown hyperpigmentation, often referred to as *brawny edema*, characteristic of the advanced stages of CVI. The associated thin, glistening skin and induration of brawny edema result from the associated fibrin cuffs and fibrosis. Already prone to ischemia and tissue necrosis, the involved areas

develop venous stasis dermatitis and attendant intense pruritus, resulting in scratching, skin breakdown, and ulceration.

#### INTRODUCTION

Surgical repair is not the standard or first-line treatment for venous stasis ulcers. The application of a firm compression garment to the involved lower leg has been used for thousands of years, and for more than 300 years, compression in one form or another has been the mainstay of treatment for venous stasis leg ulcers and CVI. As early as the 1600s, a rigid lace-up stocking was used, but it was not until the mid-1800s that elastic bandages were invented and used for treating this condition. Multiple forms of compression therapy are available today, including hosiery, bandages, boot systems, orthotics, pneumatic pumps, and various combinations of these.

The exact mode of action of compression is not fully understood, but the theory is that pressure applied to the calf muscle raises interstitial pressure, reduces venous insufficiency, lowers superficial venous hypertension, and facilitates venous return by supporting the calf muscle pump. Additional proposed benefits associated with compression therapy include the softening of lipodermatosclerosis, reduction of venous reflux, increase of arterial flow to the ulcer site, improvement in the microcirculation, increased oxygenation to the wound site, and stimulation of fibrinolysis. In short, continuous compression decreases venous congestion, lowering retained volume in the lower extremities and facilitating a favorable wound healing environment.

This chapter considers only one frequently used type of compression therapy, the Unna boot. It is important to understand that other compression systems are commercially available and effective for the treatment of venous stasis ulcers. Although the Unna boot is favored in the United States, the multilayered elastic compression bandage or wrap is more popular in the United Kingdom. Short stretch bandages are widely used throughout the remainder of Europe, as well as Australia. Which type of compression is the most effective remains unclear from a review of the most current evidence-based literature (see Bibliography). What is clear is that compression is more effective than no compression, high compression is more effective than low compression, and multilayered systems are more effective than single-layer systems.

The Unna paste boot is used primarily when a semi-immobilizing, soft-pressure or gradient-pressure dressing over a joint, extremity, or even the scalp is needed. It is commonly available in a 3- or 4-inch roll or bandage that is impregnated with a calamine–gelatin–zinc oxide compound (Fig. 41-1). Unna paste dressings are soothing and antipruritic and require less frequent dressing changes than

**Figure 41-1** Examples of commercial Unna paste boot materials. (Courtesy of Dynarex Corporation, Orangeburg, NY.)

conventional dressings. When dressing changes can be scheduled from 3 to 11 days, instead of one to three times per day, savings in health care cost and patient convenience can be realized.

#### **INDICATIONS**

- Phlebitis and thrombophlebitis of the lower extremity
- Venous stasis ulcers
- Postphlebitic syndrome
- Lymphedema
- Split- and full-thickness skin graft sites
- Split- and full-thickness skin graft donor sites
- Acute and chronic tendonitis
- Acute ankle sprains without fracture

Use of the Unna paste dressing has varied over the years. With the advent of air cushion or foam splints, its use for ankle sprains has diminished. Unna paste dressings continue as a therapeutic mainstay for chronic venous disease with or without venous stasis ulcers. Without some type of dressing, healing-associated pruritus can lead to scratching and subsequent enlargement of the ulcers. The Unna boot can be used as a symmetric gradient-pressure dressing for venous stasis ulcers to help reduce venous hypertension, control edema, and counteract delayed venous return. As such, the Unna boot is a proven, effective part of overall therapy. Débridement should be carried out before application, if indicated, and then the ulcer should be covered with a permeable dressing, such as Tegaderm (pouched or regular).

Recent studies have advocated Unna paste dressings over splitor full-thickness skin grafting of burns on extremities. The advantages of using the Unna paste dressing compared with conventional dressing changes two to three times per day include earlier hospital discharge, patient comfort (because of fewer painful dressing changes), and higher graft acceptance rate (nearly 100% in some studies, probably because of less graft disturbance during critical microcirculation formation).

Unna paste dressings have been used over skin graft donor sites on the scalp. Use on scalp donor sites led to a significant reduction in a complication called *concrete scalp* (thick exudative crusting over the hair-bearing scalp, which tends to scar).

When pediatric patients excoriated their lower extremity skin grafts because of pruritus, the Unna paste dressings allowed healing and higher percentage skin graft acceptance. Parents spent less time changing the dressings (15 minutes vs. 3.5 hours per week), and the children had fewer play- and sleep-time disturbances compared with conventional three-times-per-day dressing changes and use of antihistamines.

When Unna paste dressings were used over skin-grafted, molten metal burns of the lower extremity, the benefits included early ambulation and earlier hospital discharge and return to work (44 vs. 84 days).

In acute and chronic tendonitis, the Unna boot acts as a soft immobilizer.

#### **CONTRAINDICATIONS**

- Acute sprains with fractures
- Significant arterial insufficiency when used with compression covering
- Venous stasis ulcers that are infected and need débridement and cleaning (e.g., ulcers with heavy exudate and crusted ulcers with associated cellulitis)
- Active superficial phlebitis if infection is a major concern
- Sensitivity to any of the dressing components

Acute fractures can continue to swell. Because the gauze in the Unna paste dressing is nondistensible, pressure sores or compartment syndrome may occur if there is marked swelling after application.

Circulatory compromise and necrosis have been reported when a compression dressing is used in the presence of arterial insufficiency. Use a hand-held Doppler and blood pressure cuff to compare the ankle and brachial pressures. The ratio of the systolic pressure at the posterior tibial or dorsalis pedis artery divided by the brachial artery pressure should be equal to or greater than 1. If the ratio is 0.7 or less, significant arterial insufficiency is present and compression is contraindicated. If infection is a concern, use of a dressing that is not changed for 3 to 11 days may mask progressive infection and postpone appropriate treatment.

#### **TECHNIQUE**

- Cleanse the skin with slightly warm water or saline. If the skin is dry, petroleum jelly can be used as a moisturizer. Avoid topical antibiotics, povidone, and hexachlorophene, which can be topically sensitizing and cause a contact dermatitis. Topical steroids can be applied after washing if dermatitis is present.
- 2. For venous stasis ulcers, débride the ulcer. Hydrocolloid dressings such as DuoDerm can aid in healing. Some experts recommend extending the DuoDerm 1 inch past the edge of the ulcer. It is normal for these moist dressings to develop an anaerobic odor that does not necessarily indicate an infection. Alternatively, the ulcer can be covered with a permeable dressing like Tegaderm.
- 3. A smooth, snug layer of Kling or Kerlix can be used as an underwrap if desired. This may prevent chafing of the skin as the Unna paste dries.
- 4. For the lower extremity, keep the ankle at a right angle. Start wrapping at the metatarsal heads and roll proximally with a 50% overlap. It is important to avoid ridges, which can cause discomfort (Fig. 41-2).
- 5. Cover the heel completely. Alternate a horizontal wrap to cover the Achilles tendon with an oblique turn to cover the posterior aspect of the heel. Cut the dressing and start another wrap around the heel. Wrap snugly and cut the dressing frequently during the wrap. Avoid applying the edge of the dressing on the joint line, instead crossing the ankle with the full width of the

**Figure 41-2** Application of first layer of Unna paste boot with zinc oxide-impregnated gauze. (Courtesy of Dynarex Corporation, Orangeburg, NY.)

Figure 41-3 Application of second layer of Unna paste boot with Ace, Coban, Kling, or gauze wrap. (Courtesy of Dynarex Corporation, Orangeburg,

wrap. This helps prevent constriction bands and their tourniquet effect. Do not reverse directions as with plaster casting material; wrap only in one direction (clockwise or counterclockwise) to prevent ridges.

- 6. Wrap the Unna paste dressing in three layers and proceed all the way to the tibial tuberosity.
- 7. Several options for covering the Unna paste dressing include elastic bandage, Coban, Kling, or stockinette. Both the elastic bandage and Coban dressing help with needed compression
- 8. The final boot will consist of two or three distinct layers in addition to the specialized wound dressing if a venous leg ulcer is present (Fig. 41-4).
- 9. For wounds that are moist and draining, the dressing may need to be changed more frequently, as often as every 3 days. If moist discharge is minimal, the dressing can be changed about every 7 days and up to 11 days for patients on protracted therapeutic regimens. For patients with new applications of the Unna boot, it is wise to examine the patient and change the dressings more frequently to ensure that there are no complications.
- 10. The Unna "cap" for a skin graft donor site on the scalp is applied with an initial layer of Aquaphor gauze followed with an Unna paste dressing. Excellent results with no "concrete scalp" complications were achieved with dressing changes every 3 days in one small study.

#### **COMPLICATIONS**

- Occasional contact dermatitis
- Neurovascular compromise if dressing is applied too tightly or in the presence of arterial insufficiency
- Masking of cellulitis developing in a stasis ulcer under the dressing

Ace, Coban, Kling, or gauze Three layers of boot Tegaderm or Opsite Skin

Figure 41-4 A, Unna paste boot, completed application. B, The layers of a completed boot application.

#### POSTPROCEDURE PATIENT EDUCATION

- The dressing must be kept dry.
- Patients should cover the entire dressing with a plastic bag or other impermeable covering to bathe.
- Remove the boot with a pair of large bandage scissors. Lifting the bandage away from the skin and applying a thin film of petroleum jelly on the scissors can prevent discomfort or inadvertent injury during removal.
- Cleanse and dry the skin thoroughly. When the boot is used for stasis ulcers, inspect the area carefully for the presence of infection and débride again if necessary before applying a second boot. Venous stasis ulcers can take 2 to 3 months or more
- For best results, the patient must comply with all other aspects of medical therapy.
- As the swelling subsides in sprains, the compression advantage will be lost. Instruct the patient to return in 2 or 3 days or when the Unna paste dressing becomes loose or develops wrinkles because these can cause pressure sores. A second boot will need to be applied, or more appropriate therapy, such as an inflated splint, must be used.
- Teach the patient to check for signs of impaired circulation and to report any paresthesia, discoloration, or worsening discomfort promptly.

#### **CPT/BILLING CODE**

29580 Unna paste boot application

(When the code 29580 is used with the modifier -22, the procedure applies to the application of a multilayered, sustained, graduated high-compression bandage system, not to the standard three-layer Unna boot application.)

#### **ICD-9-CM DIAGNOSTIC CODES**

- 451.0 Phlebitis or thrombophlebitis, superficial vessels of lower extremities
- 451.1 Phlebitis or thrombophlebitis, of deep vessels of lower extremities
- Phlebitis or thrombophlebitis, femoral vein (deep) 451.11 (superficial)
- 451.19 Phlebitis or thrombophlebitis, other
  - Femoropopliteal vein, popliteal vein, tibial vein
- 451.2 Phlebitis or thrombophlebitis of lower extremities, unspecified
- 454.0 Varicose veins of the lower extremities with ulcer
- 454.1 Varicose veins of the lower extremities with inflammation (stasis dermatitis)
- 454.2 Varicose veins of the lower extremities with ulcer and inflammation
- 457.0 Noninfectious disorders of lymphatic channels
- 457.1 Lymphedema, acquired
- 459.1 Postphlebitic syndrome 459.11
- Postphlebitic syndrome with ulcer
- 459.12 Postphlebitic syndrome with inflammation
- 459.13 Postphlebitic syndrome with ulcer and inflammation

В

#### 266 DERMATOLOGY

707.0	Decubitus ulcers
707.06	Decubitus ulcers, ankle
707.07	Decubitus ulcers, heel
707.09	Decubitus ulcers, other site
707.10	Ulcer of lower limb, unspecified
707.11	Ulcer of thigh

707.11 Ulcer of thigh

707.12 Decubitus ulcers, calf

707.13 Ulcer of ankle

707.14 Ulcer of heel and midfoot, or plantar surface of midfoot

782.3 Edema, legs

825.25 Metatarsal fractures

Some Medicare Carriers (MC) and Fiscal Intermediaries (FI) specify the diagnoses that support medical necessity for CPT 29580. One MC in Arkansas will cover Unna boots only for ulcers of the lower extremity (454.0, 454.2, 707.06, 707.07, 707.12, 707.13, and 707.14). Other MCs and FIs will accept a wider set of ICD-9-CM codes, so it is advisable to consult their written Articles and Local Coverage Decisions to ascertain what codes are covered in a specific locale.

#### **SUPPLIERS**

(See contact information online at www.expertconsult.com.)

Unna Paste Boot dressing is a trade name, and more than 25 companies make these dressings. Check with your local medical supply company or contact one of the following:

## WART (VERRUCA) TREATMENT\*

Lori Oswald • John L. Pfenninger

Warts are a disease of antiquity. They have no regard for class or social status. They do not discriminate by race or color. There is an equal political distribution between Republicans and Democrats. They are annoying, sometimes disfiguring and painful, and to the angst of patient and physician, they frequently recur. With ardent attempts to rid the pest by heating, freezing, burning, cutting and electrifying, treatment has induced as much anxiety as the disease itself. But the physician persists.

William C. Everts, DO

Verrucae vulgaris (warts) are caused by the human papillomavirus (HPV). There are over 100 individual types and they are identified by numbers. Common warts are caused by types 1, 2, 4, 7, 27, 29, and 57; flat (planar) warts, by types 3, 10, 28, and 49; and plantar warts, by types 1, 2, and 4. Another series of HPV cause cervical dysplasia and condylomata. Most verruca vulgaris lesions form after a latent period of weeks to several months. The peak incidence occurs in late childhood and adolescence.

HPV causes numerous epithelial cancers. Cervical dysplasia and cervical cancer are the most commonly recognized types. However, 31% of squamous cell carcinomas and 36% of basal cell carcinomas of the skin contain HPV in nonimmunosuppressed patients. In immunosuppressed patients, 65% of squamous cell carcinomas and 60% of basal cell carcinomas contain HPV. As a result, treatment becomes more than just a cosmetic issue.

Warts have the following various presentations:

- Flat (planar)
- Filiform (small, fine, elongated lesions)
- Mosaic (a cluster of warts that fuse together)
- Verruca vulgaris, including periungual ("common wart")
- Plantar
- Genital/anal wart (condylomata acuminata)
- Laryngeal papillomatosis

#### **DIFFERENTIAL DIAGNOSIS**

- Actinic keratosis
- Seborrheic keratosis
- Nevus
- Molluscum contagiosum
- Callus
- Corn
- Nonspecific papule
- Cutaneous dysplasia

It can be difficult to differentiate the true nature of a plantar lesion. Hypertrophic callus buildup makes identification confusing. The tell-tale sign of a plantar wart is that, as the callus is pared away, the practitioner sees small, punctate sites of bleeding. This is nearly pathognomonic for HPV disease. Biopsies can be obtained when the diagnosis remains unclear.

#### INDICATIONS FOR TREATMENT

- Pair
- Bleeding
- Recurrent trauma
- Lack of spontaneous resolution
- Psychosocial sequelae
- Employment repercussions (e.g., waitress)
- Rapid growth or multiplication
- Concerns regarding transmission
- Persistence as a possible cause of malignancy

A large number of verrucae do not resolve spontaneously. A longitudinal study concluded that only 40% of patients cleared their warts over a 2-year follow-up. HPV can remain dormant for long periods, then suddenly grow rapidly or multiply. With any treatment, the role of the immune system should not be underestimated. Induced inflammation from whatever treatment modality is used may finally trigger the immune system to recognize and then resolve the virus.

The virus itself is never totally eliminated. Rather, the immune system merely keeps it in remission, much like herpes. The virus can recur with any immunosuppressed state at any time during the patient's life. The goal of treatment is to eradicate active disease, not to eliminate the virus itself.

#### **CONTRAINDICATIONS**

- Lack of compliance
- Cellulitis
- Allergy to treatment modality
- Ambiguous diagnosis
- Bleomycin in the very young (relative)

#### **TREATMENT**

See Box 42-1 and Figure 42-1.

#### **General**

Transmission of HPV occurs by direct person-to-person contact or, possibly (and rarely), from fomites. The patient may also cause autoinoculation of verruca vulgaris by scratching, shaving, or traumatizing the skin. It is important to *enhance the immune system* as much as possible during the treatment of all wart manifestations. Smoking is known to increase the growth potential and the persistence of warts on the cervix. Smoking reduces the cells of Langerhans in the skin in general and subsequently decreases all immunity.

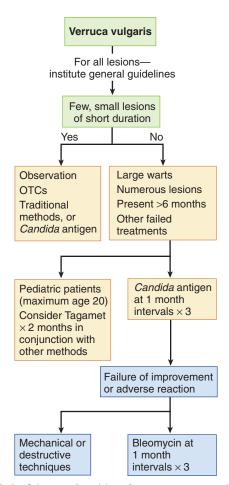

<sup>\*</sup>For the treatment of genital warts (condyloma), see Chapter 155, Treatment of Noncervical Condylomata Acuminata.

#### Box 42-1. Modalities for Treating Warts (Verruca Vulgaris) General guidelines (maintaining healthy immune system) Eating a diet high in fruits and vegetables Taking vitamins with folic acid (may supplement folic acid up to 1 mg) Avoiding smoking and secondhand smoke Avoiding any immunosuppression when possible Expectant observation Hypnosis Chemicals: topical Over-the-counter medication (usually an acid preparation) Topical salicylic acid 17%–40% Formalin Cantharidin (Cantharone) 0.7% collodion solution Trichloroacetic acid Bichloracetic acid Tretinoin (Retin-A 0.05% solution, or 0.025%, 0.05%, or 0.1% cream) 5-Fluorouracil (Efudex, Fluoroplex) 5% cream Imiquimod (Aldara) Podofilox (Condylox) Silver nitrate Chemicals: oral Cimetidine (Tagamet) 20-40 mg/kg/day (especially in pediatric patients) Zinc sulfate 10 mg/kg to maximum of 600 mg/day (three divided doses, 2 mo maximum) Chemicals: injection Candida antigen (Candin) 1:500 solution or generic 1:1000 solution Bleomycin (Blenoxane) 15-U vial Interferon Mechanical Tape occlusion Cryotherapy Liquid nitrogen (-196° C) Nitrous oxide (-89° C) Carbon dioxide (-78° C) Tetrafluoroethane (-47° C/-70° C): MediFrig, Verruca Freeze Dimethyl ether/propane (-29° C/-55° C): Histofreezer, Compound-W, Wartner, Dr. Scholl's Electrodesiccation and curettage Electrocautery (ball electrode) Laser Infrared coagulator (IRC) Radiofrequency loop removal Excision (discouraged) Also see Chapter 155, Treatment of Noncervical Condylomata

The patient must be advised to *stop smoking* (if applicable). *Illicit drugs* have been known to suppress the immune system and they, too, should be avoided. On the other hand, various *vitamins* (e.g., folic acid) have been shown to play a beneficial role in suppressing HPV. Subsequently, consider using a good multivitamin with minerals to maximize immune system capabilities. The patient should also be instructed to eat a *diet* that includes five helpings of fruits and vegetables a day to optimize immune function. Medications such as *steroids* that suppress immunity should be limited, if at all possible.

Acuminata.

Treatment of verrucae in patients who are pregnant, have had organ transplants, are immunosuppressed as a result of diseases such

**Figure 42-1** Selection of modalities for treating verrucae. At each visit, reinforce general guidelines. At times, especially with extensive lesions, bleomycin and *Candida* antigen can be injected at the same visit (use separate syringes). *Candida* and bleomycin may need to be used more than three times. As long as progress is being made, there is no need to change treatment. OTC, over the counter.

as acquired immunodeficiency syndrome, or are taking immunosuppressants of any sort is difficult. Patients should be made aware that the success rate in such cases is poor.

Research into the efficacy of various treatments for warts is difficult. Some studies have shown that even hypnosis can resolve warts. Many folktales carry the belief that banana peels, raw potatoes, cerumen, spider webs, and other items resolve warts. Spontaneous resolution is always possible and often occurs for no apparent reason.

Many physicians recommend expectant observation. An old maxim states that "wart" patients should not be referred to a physician friend for treatment because it will generally make the physician look bad! Anyone who has treated warts can become frustrated in dealing with them. Not only can they persist, but they may indeed multiply. Frequently, treatment of a single wart with a modality such as cryotherapy or cautery will result in a ring of warts around the area that was frozen or burned. The simple common wart has indeed humbled the best clinicians. Subsequently, many again recommend simple observation.

Warts have no "roots" and are completely epidermal lesions. Treatment ideally should not cause scarring. There is no communication between warts—no "mother wart!" However, treatment of a single wart or some of the warts can lead to resolution of all the warts because of immune activation. Obtaining patient compliance for any regimen is often difficult, and home remedies frequently fail

owing to lack of consistency in applying the treatment. It is not uncommon for a physician to have to treat a lesion(s) four or more times to resolve it.

#### **Chemicals: Over-the-Counter Medications**

Numerous over-the-counter (OTC) medications, usually mild acids in liquid form, are available for the treatment of warts. These include Compound-W, Mediplast, Trans-Ver-Sal, Occlusal, Duofilm, Premier, Salactic Film, Sal-Plant gel, Tinamed, Wart Off, and Duoplant. Forty percent salicylic acid treatments (Compound-W maximum-strength pads, Dr. Scholl's clear-away maximum-strength pads and invisible strips) may also be used and applied every 48 hours. (See also the discussion of "Tape Occlusion" in the section on "Mechanical Methods.")

Method: Pare away callus after soaking lesions in warm water. Hydrating the keratin allows better penetration of the liquid or agent being applied. Apply medication as directed by supplier and occlude the area. Repeat every other day, being sure to remove the dead tissue with paring or with a pumice stone. Treatment is nonscarring and generally effective but requires compulsive persistence with daily treatments, often for 4 to 6 weeks.

#### **Chemicals: Physician Applied**

#### Bichloracetic or Trichloroacetic Acid (50% to 85%)

These are potent chemicals and should not be provided for home treatment.

Method: Prepare the lesion as described for OTC medications. Apply the acid, being careful to avoid normal skin. If the lesion is raised and convoluted, work the acid into the lesion with a toothpick. Cover. Repeat weekly until the wart has resolved.

#### Cantharidin (Cantharone, Verr-Canth)

Cantharidin causes blistering at the dermoepidermal junction.

Method: Apply the chemical directly on the wart and cover it with tape for 48 hours. Evaluate the patient weekly and remove any residual blister, then reapply the cantharidin. Repeat until the wart has resolved.

#### Silver Nitrate

*Method:* Silver nitrate is available on the ends of sticks. Apply after paring as for OTC medications. Repeat weekly. Unfortunately, this method can leave a dark chemical "tattoo" that usually resolves but may last for months or years.

#### **Prescription Creams**

#### Tretinoin Cream (Retin A)

Method: Cream or solution at a concentration of 0.025%, 0.05%, or 0.1% is rubbed in thoroughly at bedtime. This is frequently used with diffuse flat warts on the legs or face, so it is rubbed over the entire area. The application may be repeated daily. The goal is to have a mild erythema with fine scaling. It is not uncommon to take months to resolve the warts. It can be used in combination with 5-fluorouracil or imiquimod.

#### 5-Fluorouracil (Efudex, Fluoroplex)

5-Fluorouracil (5-FU) is a second-line treatment for truly resistant warts, and it has not been approved by the U.S. Food and Drug Administration (FDA) for this indication.

Method: A 2% solution or 5% cream is applied similarly to tretinoin cream. It is important to rub in thoroughly. 5-FU can also be used for condylomata (see Chapter 155, Treatment of Noncervical Condylomata Acuminata). 5-FU can cause significant inflammation in intertriginous areas and in areas with actinic skin change.

#### Imiquimod (Aldara)

Imiquimod is not a caustic agent but rather an immune enhancer. It is supplied in boxes of 12 or 24 packets. It is not approved by the FDA for verrucae (only for condylomata in those 12 years of age and older), but is frequently used as the sole treatment or as an adjunct in combination with other treatment therapies. It is essential to pare down the callus (especially on a plantar wart) and to rub in the imiquimod thoroughly. For verruca, it is applied *daily*, usually in the evening before sleep, and removed after 8 hours. It is not necessary to discard a packet if only a portion is used.

#### Podofilox (Condylox) Liquid

Refer to Chapter 155, Treatment of Noncervical Condylomata Acuminata.

#### Chemicals: Oral

#### **Oral Cimetidine (Tagamet)**

Method: Although controlled studies in children included small numbers, cimetidine appears to resolve verruca in some cases with dosages of 20 to 40 mg/kg/day for 2 months maximum. It can be used in addition to other caustic modalities to accentuate efforts. One study showed that adults with recalcitrant warts could be treated successfully with doses of 30 to 40 mg/kg (maximum dose of 3.5 g/day).

#### Oral Zinc

Zinc sulfate taken orally at 10 mg/kg/day to a maximum of 600 mg in three divided doses has been reported to result in complete resolution of resistant warts in 60.9% after 1 month and in 86.9% after 2 months. However, patients generally become nauseated and 20% experienced vomiting, which limits its overall acceptance.

#### **Chemicals: Injected**

#### Candida Antigen

**EDITOR'S NOTE:** After OTC topicals, this method is my absolute first choice to treat all but the simplest verrucae. I have not tried it on condylomata. It can be used on single large warts, on mosaics, or to treat patients with 80 to 100 lesions! I have used it for 18 years now, and results are excellent with few adverse reactions and no scarring. Multiple studies confirm its effectiveness.

Candida antigen is used for verruca vulgaris (nongenital HPV; Fig. 42-2). It has not been studied on condylomata acuminata. Although Candida antigen has been approved for over 40 years as the control

**Figure 42-3** Examples of verrucae that are difficult to treat, but are well suited to *Candida* antigen injections: Periungual (**A**); large finger lesion (**B**); mosaic, toe and plantar aspect of metatarsal head (**C**); multiple lesions on the hand of a patient who had both hands affected (postinjection) (**D**).

for tuberculosis testing, it does not have FDA approval for treating verrucae. Its use is nevertheless covered by malpractice policies even when treating warts. *Candida* antigen can be especially helpful for large, extensive lesions, multiple lesions, and periungual lesions where other modalities would cause too much trauma (Fig. 42-3).

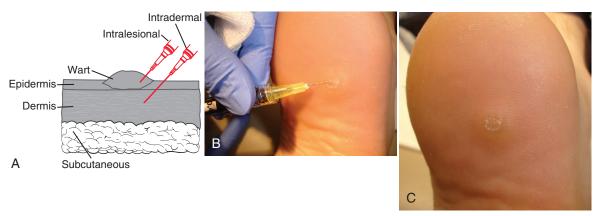

The concept is that nearly everyone has antibodies to *Candida*. When the antigens are injected into an area, there is an immediate immune response (redness, some swelling, occasionally mild pruritus). The increased immune activity in the area leads to recognition of the foreign material of the verruca, and an immune response ensues against that antigen as well. The body is then "sensitized" to the wart and eliminates all such lesions.

#### Pfenninger Protocol

- Candida antigen is available as Candin (1:500) and as a generic (1:1000). Caution: Some allergy desensitization extracts may be in concentrations as high as 1:50, which can cause excessive reactions.
- Mix 1:1 Candin and lidocaine 1% or 2% without epinephrine, or 1 part generic antigen with 4 parts lidocaine. (In spite of its lower concentration, the generic preparation appears to cause more reaction and thus needs greater dilution.)
- Topical anesthetic may be applied 15 minutes before injection.
- Inject 0.1 to 0.3 mL per wart (depending on size), using a 30-gauge needle and 1-mL Luer-Lok syringe. The Luer-Lok (screw-on) connection is important because it often takes considerable pressure to inject the solution into the wart/skin. This can cause a needle that is just pressed on to come off, spraying fluid everywhere.
- Try for an *intradermal* or *intralesional* injection to create an immune response. If the solution goes in easily, it is in too deep. Create a bleb if possible. Wear protective glasses because the material often "squirts" out through a verruca pore (Fig. 42-4).

- Limit the total amount to 1 mL at any one visit. If there are numerous warts, this may mean injecting only minute amounts into each one. Even if all the warts are not injected individually, the immune response may generalize and all warts may disappear.
- Repeat injection in 1 month if residual tissue remains.
- If the injections have not worked after three attempts 1 month apart, then they probably will not be successful. However, when warts are extensive, there are not many other options. As long as there is some progress, results have been obtained even after five or six monthly injection sessions.
- Expect 65% to 75% effectiveness with the first injection. Of the remainder, approximately 50% respond with each succeeding injection.
- Expect pruritus, drying of the lesion, and peeling of dead tissue.
   The lesion may turn black, regress spontaneously without any outward signs, or become erythematous (localized).
- Adverse reactions include rash (allergy), adenopathy, and persistence of the lesion, all very rare.

The advantages of the Candida antigen injection are that if the immune system can be activated to recognize the foreign tissue, all lesions will resolve. Allergic reactions are extremely rare. There is usually none of the scarring, hyperpigmentation, or hypopigmentation that can occur more commonly after some of the other modalities of treatment. There is no "downtime"; patients can exercise, play sports, go back to work, and do whatever they want immediately after treatment. There is minimal pain. The pain at the time of injection can be reduced through the use of the MadaJet to inject the solution (see Appendix H, Pearls of Practice). However, expensive solution is lost just to prime the "gun." The real advantage to using Candida antigen is that, unlike many of the other modalities, the immune system is induced into responding and resolving the lesion(s). Recurrences are rare, and efficacy is 80% to 85% after

**Figure 42-4** Injecting *Candida* antigen for the treatment of warts. **A,** Intralesional injection and intradermal injection. If injected into the subcutaneous tissue, the level is too deep. **B,** Injecting a heel lesion. **C,** Appearance postinjection.

three treatments at monthly intervals. It can be used in combination with almost all of the other treatment modalities to effect a synergy between the agents.

Proprietary *Candida* antigen is expensive, but a generic form is available. Practitioners often supply the antigen for the first visit, but write a prescription for the patient to bring the antigen in at subsequent visits. Outpatient hospital pharmacies usually carry it, but any pharmacy can order it. This markedly reduces costs for the clinician's office. Insurance companies generally do not reimburse the physician as there is no J code, but they will commonly pay for the patient's prescription. Note on the prescription, "Bring to the next office visit, for treatment of warts." Some insurance companies will not pay if it is being used for diagnostic purposes.

The most critical aspect of treatment is to inject the solution into the lesion itself or intradermally just below it. Do not go below the dermis. The injection should be difficult; if the solution goes in easily, the placement is too deep.

For a more complete review of the entire procedure, go to www.altoonafp.org/wartstudy.

#### Bleomycin

When all other methods fail, intralesional bleomycin can be considered. Pregnancy must be excluded before bleomycin injection is performed.

Method: A 15-U vial of bleomycin sulfate (Blenoxane; Bristol-Myers Squibb, Princeton, NJ) is diluted with 5 mL of bacteriostatic water or 0.9% sodium chloride to form a 3-U/mL solution. When stored at 4° C, the solution can be used for up to 4 months. Mix one part of this solution with five parts of 1% lidocaine without epinephrine (i.e., 0.1 mL of bleomycin with 0.5 mL of lidocaine). This provides 0.6 mL of solution with 0.5 U bleomycin/mL. Use a 30-gauge needle. Inject directly into the wart as follows:

Wart Size	Amount of Solu	tion (0.5 U	Bleomycin/
Wart Size	Amount of Solu	tion (0.5 U	Bleomycin/

Multiple warts Up to 3 mL (1.5 U)/visit

Warts will initially appear hemorrhagic, then clear (48% to 92%; Fig. 42-5). Repeat injection can be performed in 2 to 4 weeks. Three to four treatments may also be required for resistant lesions. Alternatively, the drug can be "dropped" onto the wart and "pricked" into the lesion using a Monolet needle. If tolerated well, the concentration of bleomycin can be gradually increased to 1:3 (bleomycin 0.5 U/mL to lidocaine).

Bleomycin is expensive. One vial will treat many patients. Patients can be given a prescription, which allows them to bring the

drug to the office and saves office expense. It is also quite painful. The main mode of action of bleomycin is the inhibition of DNA synthesis, with some evidence of RNA inhibition. When injected locally it causes vascular microthrombosis; therefore, the patient may develop a hemorrhagic blister and may want it drained if the blister becomes uncomfortable. There have been very rare reports of Raynaud's phenomenon occurring after intralesional injection of bleomycin.

**EDITOR'S NOTE:** We have used bleomycin extensively for 10 years, treating five or six patients per week in a referral clinic. We have never seen Raynaud's phenomenon as a complication when using bleomycin as described.

#### Interferon

Alfa interferon is approved by the FDA for treatment of condylomata in patients older than 18 years of age. Two preparations are available:

- Alferon N injection (interferon alfa-n3): 1-mL vial, 0.05 mL/wart injected two to three times per week for up to 8 weeks
- Intron-A (interferon alfa-2b): 10 million IU/vial, 0.1 mL (reconstituted) per wart three times per week for 3 weeks

Some practitioners use interferon for verrucae as well. It is expensive and can often be followed by flulike symptoms for 24 hours. Subsequently, its use is quite limited. For more details on interferon use, see Chapter 155, Treatment of Noncervical Condylomata Acuminata.

Figure 42-5 Bleomycin response 3 days after injection.

#### **MECHANICAL METHODS**

#### **Tape Occlusion (Patient Applied)**

For young children or for those who are afraid of needles, tape occlusion can be tried. However, in contrast to initial reports, recent studies have shown treatment with tape to be only 16% to 21% effective. The wart is simply covered with tape (usually duct tape) for a week. Tape is removed for 12 hours and then reapplied. The patient is seen 1 week later and macerated tissue is removed. The cycle is repeated until the wart(s) resolves, usually in 4 to 6 weeks. Obviously, this method is useful only if there are a limited number of lesions and if there is patient compliance. One of the major difficulties is keeping the tape in place.

## Cryotherapy (Over-the-Counter and Physician Applied)

Cryotherapy is a destructive treatment of the skin because the cold by itself does not kill HPV. The real advantage to cryotherapy is that there is little disability and usually no scarring. The patient may initially experience localized erythema and edema, followed by blister formation. Some persistent hypopigmentation may occur. Cryotherapy with liquid nitrogen is usually performed using a thermos bottle spray unit or cotton-tipped applicators (Fig. 42-6). OTC "freeze treatments" are also available. They contain dimethyl ether and propane, but they are not as effective because they do not reach as cold a temperature as liquid nitrogen (–196° C). Examples of these products are Compound W-Freeze Off, Wartner-Freezing Wart Remover, and Dr. Scholl's Freeze Away (also makes a combination kit with salicylic acid). See Chapter 14, Cryosurgery, for further details.

## **Electrodesiccation and Curettage or Electrocautery**

Warts can be treated readily with electrocautery. Small ones can be touched with the battery-powered "hot wires" and wiped away. Similarly, electrical units can be placed on fulguration or coagulation settings and the warts coagulated with the ball tips. It helps to have them moistened first. Smaller lesions can be grasped with metal pickups and the current transferred to the wart by touching the cautery tip to the forceps.

All lesions need to be anesthetized. Keratin (such as in plantar warts) must be pared away because it has little moisture and does not coagulate readily. That is why many practitioners curette the wart first and then coagulate the base. Bleeding from the curettage is controlled with digital pressure.

The major complication from electrodestruction is scarring, which occurs to some degree in all areas treated this way except for the very small superficial lesions. The provider must be especially careful on the plantar surface of the feet not to create a hypertrophic scar. This can become a persistently painful area analogous to walking on a stone in a shoe.

The greatest advantage of using curettage before electrocautery is that the abnormal tissue will usually separate from normal skin, defining what is abnormal from the normal tissue. A sharp disposable curette is needed; reusable curettes are often too dull. Unfortunately, the disposable curettes frequently bend. The Curetteblade (see Chapter 32, Skin Biopsy) is sharp and strong, so it does not bend. Cautery is then applied, and repeat light curettage is performed. This limits excessive removal of normal tissue and scarring. Alternatively, large warts can be shaved off to debulk them before cautery, but this will leave a significant amount of wart tissue behind and make cautery more difficult.

Primary excision using radiofrequency loop removal (see Chapter 30, Radiofrequency Surgery [Modern Electrosurgery]) is to be discouraged because the loop cuts so rapidly that it is easy to overexcise the lesion and leave a large pit and subsequent scarring. Tendons, nerves, and periosteal tissue can be injured inadvertently even by the experienced practitioner. It is critical to be familiar with the relevant anatomy when using any of the electrocautery techniques.

Of all methods, the electrocautery technique is one of the most effective. However, it has the disadvantages of prolonged healing with an open sore, scarring, and pain.

#### **Laser Method**

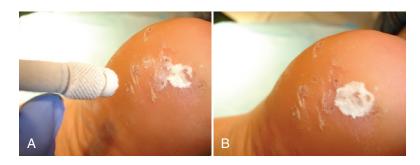

The laser method is expensive but offers the advantage of precise control of depth and removal of "just the right amount" of tissue. When properly used, results are excellent and scarring is minimal. Combining pulsed-dye laser with the application of salicylic acid has been shown to decrease the number of laser treatments needed.

#### **Infrared Coagulation (Redfield)**

One of the more recent treatments for warts—another method of destruction—is the use of the infrared coagulator. It is quick and effective. Much of the research has been done on condylomata. The probe is placed on the wart for 0.75 to 1 second, and the trigger is pulled. Local anesthesia is necessary. Blistering followed by sloughing and then superficial ulceration can be expected. Scarring is possible. See Chapter 106, Office Treatment of Hemorrhoids, for discussion on the use of the infrared coagulator.

#### **Excision**

Many pedunculated and filiform warts can be grasped with pickups and quickly excised with sharp tissue scissors, a curette, or a blade (shave excision). Consider using *Candida* antigen with lidocaine mixed per the Pfenninger protocol as the local anesthetic before excision to promote resolution of the wart. This is treating the wart with two different modes. After removal, cauterize the base lightly, not only to control the bleeding but to destroy any residual wart tissue. It is only in the extremely rare case of an isolated wart or two that has resisted everything that full-thickness skin excision with suture placement is necessary. This is especially discouraged on the

**Figure 42-6** Treating a plantar wart with liquid nitrogen. **A,** Freezing the wart. **B,** Appearance after cryotherapy.

TABLE 42-1 Treatments of	Choice Listed in Order of Preference	ce
	Primary	Secondary
Filiform wart	STS excision	Electrocautery, cryotherapy, curettement
Flat warts (planar)	Candida antigen	Tretinoin, 5-FU, cryotherapy
Verruca		
Single or few, small	Cryocautery/Candida antigen	Electrocautery
Multiple	Candida antigen	Cryocautery
Mosaic	Candida antigen	Cryocautery
Plantar	Candida antigen	Cryocautery
Periungual	Candida antigen	Cryocautery
Resistant to Candida $\times$ 3	Bleomycin injection (off-label)	Cryocautery, electrocautery, IRC
Condylomata*	85% TCA	Radiofrequency loop excision, IRC, cryotherapy, imiquimod
Urethral meatus*	5-FU	STS excision; electrocautery
Vaginal*		
Few	85% TCA	Electrocautery, nitrous oxide cyrotherapy
Multiple	Imiquimod, 5-FU (both off-label)	Laser
Anal, vulvar*	85% TCA	Imiquimod, radiofrequency excision, cryocautery, IRC
Rectal*	85% TCA	Cryocautery, electrocautery, imiquimod, radiofrequency excision
Laryngeal papillomatosis	Laser	Mumps or candida antigen (injection; off-label)

<sup>\*</sup>Also see Chapter 155, Treatment of Noncervical Condylomata Acuminata.

plantar surface of the feet because painful scarring can be a significant complication.

Table 42-1 shows the optimal methods of treating various wart presentations. OTC medications are often tried first. Treatments also can be combined to improve outcomes.

## COMBINATION THERAPY FOR RESISTANT WARTS

- Candida antigen solution for treatment and anesthesia followed by cryotherapy.
- Imiquimod (Aldara) cream or 5-FU cream can be used in addition to most therapies (especially Candida antigen injection). If mechanical methods are used, it will be necessary to allow some healing before applying the cream. The creams may be used immediately after paring away the hyperkeratotic tissue on plantar warts, however, and will be more efficacious if the callus is removed.
- Oral cimetidine (Tagamet) can be added to any regimen.
- For extensive lesions (e.g., entire planter surfaces) Candida antigen injections can be used for some lesions along with bleomycin for other lesions.
- Always reinforce a good diet and folic acid supplements with any treatment. Zinc can also be considered alone or in addition to any treatment modality, but is poorly tolerated.

#### **FURTHER TREATMENT OPTIONS**

Because of the quest for the most efficacious treatment, multiple other treatments have been tried, including the following. Only limited studies have been done to determine their effectiveness:

- Zinc sulfate orally at 10 mg/kg daily, up to 600 mg/day in three divided doses (61% with complete clearing)
- Garlic extracts topically
- Cidofovir (Vanicream) topically

#### **COMPLICATIONS**

- Allergic reactions
- Infection
- Blistering
- Scarring
- Persistence of lesion

- Pain
- Bleeding
- Traumatic seeding and increase in number of warts

#### **CPT/BILLING CODES**

#### Intralesional injection

11900 Up to and including 7

11901 Over 7

For injections there is also generally a charge for the medication used, but there is no J code for *Candida* antigen. The provider is advised to provide a prescription to be taken to the pharmacy by the patient (see text).

The J code for bleomycin is J 9040. However, it may be advisable to give the patient a prescription to be filled, as is done with *Candida*.

### Destruction (electrocautery, cryotherapy, laser, chemicals, and curettement)

## WOOD'S LIGHT EXAMINATION

Roberta E. Gebhard

The Wood's lamp ("black light") produces ultraviolet rays with a wavelength of 365 nm and above by projecting a beam of light through a filter of glass containing nickel oxide. Invisible light in the long-wave ultraviolet range and visible blue-white light are created. The fluorescence produced as the light hits objects varies in color depending on qualities of the surface itself. Characteristic appearances have been described for several dermatologic conditions. The Wood's light examination provides a quick, inexpensive, and useful adjunct in their diagnosis (Fig. 43-1).

Diagnostic uses for the examination include the following:

- Tinea capitis
- Erythrasma
- Vitiligo, albinism, tuberous sclerosis, and other pigmentary conditions
- Pseudomonas infections
- Porphyria cutanea tarda
- Tinea versicolor
- Detection of some chemicals that are applied to the skin or taken systemically
- Adjunct in finding corneal abrasions or herpetic corneal lesion
- Identification of ejaculate in rape/sexual assault

#### **INDICATIONS**

- Any dermatitis in body folds such as the inguinal, perianal, interdigital, axillary, or inframammary areas (e.g., erythrasma, Pseudomonas infections)
- Patches of scalp scaling and partial hair loss, especially when the hairs are broken or shorter than normal (tinea capitis)
- Pigmentary conditions
- Blisters or punctate erosions on the exposed portions of the hands and forearms, with follow-up urine examination (porphyria cutanea tarda)
- Patches of scaling and altered pigmentation of the skin (tinea versicolor)

#### **TECHNIQUE**

Let the light warm for a few minutes. From a distance of approximately 8 inches, focus the Wood's light on the area of interest. Darken the room to improve visualization of the resultant fluorescence. Observe and record findings carefully. It is crucial to observe the specific color of fluorescence, not simply its presence. Soaps, lotions, cosmetics, urine, other chemicals, and fragments of scaling skin may themselves yield fluorescence. In addition, *patients should not bathe 24 hours before the examination*. Otherwise the examination may show little or no fluorescence.

#### **COMMON FINDINGS**

- Tinea capitis: The majority of cases in the United States are caused by Trichophyton tonsurans, which does not fluoresce. Trichophyton verrucosum does not fluoresce either. Hair (but not the skin of the scalp) may fluoresce yellow-green if infected with Microsporum canis or Microsporum audouinii, or a pale white-green in the rare event of Trichophyton schoenleinii infection. In these cases, sensitivity may be relatively low. Sensitivity of approximately 50% has been reported for M. canis (Kefalidou and colleagues, 1997). Fluorescence of affected hair should be sought, particularly in the follicular portion of the hair. Potentially infected, broken-off hair may be plucked and the subepidermal portion then viewed under the Wood's lamp (Fig. 43-2).
- Tinea corpora: Fungal infections of the skin do not fluoresce, except for tinea versicolor (usually a golden yellow).
- Erythrasma: This produces a brilliant coral-red fluorescence. Erythrasma, frequently confused with tinea, is not fungal in origin but is caused by Corynebacterium minutissimum. Treatment is with erythromycin (Fig. 43-3).
- Pseudomonas infection: This fluoresces aqua-green or white-green.
   Wood's light examination can be used to screen burned patients because infection fluoresces before it becomes clinically apparent.
   Pseudomonas can also be found in ear discharge, intertrigo pedis, and secondary pseudomonal infection of the scrotum.
- Vitiligo: Wood's light accentuates hypopigmented areas and is particularly useful for examining patients with fair complexions.
- Tuberous sclerosis: Wood's light is helpful in highlighting characteristic hypopigmented skin lesions exhibiting the shape of a mountain ash leaf.
- Tinea versicolor: This produces a pale yellow-gold fluorescence. In this case, Wood's light helps to differentiate skin lesions such as vitiligo.
- Porphyria cutanea tarda: Urine fluoresces a bright pink-orange. This may be accentuated by acidifying the urine, adding an equal volume of 1.5 N HCl (Fig. 43-4).
- Tetracycline: In patients taking tetracycline systemically, some inflammatory lesions (including acne papules) may exhibit a yellow fluorescence under the Wood's lamp. This fluorescence may also be observed in dried or concentrated urine containing the drug.
- Fluorescein: The dye is used topically by moistening a small strip of impregnated paper (available commercially) and allowing a drop to fall in the conjunctival sac. Any areas of denudation (e.g., trauma, herpes) on the cornea then fluoresce when viewed through the Wood's lamp (Fig. 43-5).
- Miscellaneous: Many cosmetics, topical medications, industrial chemicals, and even urine may be detected on the skin by their fluorescence. For this reason, the Wood's lamp is most useful for identifying areas for collection of samples for further forensic study in cases of suspected sexual abuse, rather than as proof of assault.

Usatine, MD, Florida State University, Tallahassee, Fla. C and D, Courtesy of Dennis Babel, PhD.)

**Figure 43-4** Urine fluoresces a bright pink-orange in porphyria cutanea tarda under Wood's light. (From Wolff K, Johnson RA, Suurmond D: Fitzpatrick's Color Atlas and Synopsis of Clinical Dermatology, 5th ed. New York, McGraw-Hill, 2005.)

**Figure 43-5** Corneal abrasion with fluorescein fluorescing under Wood's light. (From Knoop KJ, Stack LB, Storrow AB, Thurman RJ: Atlas of Emergency Medicine, 2nd ed. New York, McGraw-Hill, 2002.)

#### **PRECAUTIONS**

- Not all tinea fluoresces.
- Patients washing before the examination may yield a false-negative result.
- Do not confuse a pathologic process with other substances, such as lint, sulfur-laden scales of skin, serum exudate, ointment, deodorants, soaps, or tetracycline.

## Wound Dressing

Marisha Chilcott

Wound management is an often overlooked and undervalued aspect of patient care. Nonetheless, wounds are a source of significant patient, family, and clinician distress, causing readmission, long-term morbidity, and avoidable mortality. This brief overview of wound care and dressing selection intends to demystify basic wound management and improve patient outcomes.

There are three basic tenets to wound management:

- 1. To get rid of the "ick" (i.e., slough, pus, and necrotic debris)
- 2. To promote healthy tissue growth
- 3. To achieve wound closure

The key steps in attaining these goals are first to prepare the wound bed and then to manage the progressive development of the healing tissue. Selection of appropriate dressings is critical to succeed in these simple endeavors, and there is no single recipe that will work for all wounds. Dressing selection is determined by the individual wound itself, the available materials, and the psyche and physical health of the patient. For example, a wound in the perineum requires very different considerations than a wound on the scalp or back. A lower extremity wound in the exact same location is very different if the patient is diabetic, has peripheral vascular disease, or is an otherwise well patient with Hansen's disease (with neuropathy).

In addition to the *general wound types* most frequently encountered (e.g., *pressure ulcers*, *venous stasis ulcers*, *nonhealing infected surgical wounds*), the clinician will occasionally have to address the recalcitrant and *fungating malignant wound* of neoplasia. These wounds may need to be addressed somewhat differently because their management objective may not be actual healing. Rather, the objective may be to maintain quality of life for the patient who must live with the open wound for the remainder of his or her life. Thus, management of odor and appearance is of greater import than achieving resolution of the wound site.

Wounds with toxins, such as those produced by brown recluse spider bites or infiltrated chemotherapeutic agents, are also treated differently in that they require aggressive, usually wide surgical débridement to remove the offending agent and limit ongoing damage to tissue.

The range of dressing choices includes a variety of materials, forms, and structures. Their individual characteristics are governed by their principal purpose, be that absorption, bacterial growth inhibition, pain relief, débridement, occlusion, compression, or simple protection. Effective management of the stages of wound healing requires an understanding of the processes and the roles potentially played by the dressings available.

#### Wounds 101

The word *wound* is defined as a break in the epithelial integrity of skin with disruption of possibly deeper tissues, including dermis, fascia, muscle, and bone. Wounds then divide neatly into acute versus chronic, and clean versus infected. The ideal wound, from the standpoint of speed of healing, cosmesis, and function, is clean and acute. An example is the classic surgical wound created in a sterile environment and approximated to maximize the probability

of primary closure. The most challenging wound, from either a patient's point of view or a clinician's management perspective, is infected and chronic. These can be decubitus sacral ulcers exposed to feces, foot injuries on the diabetic patient with severe tinea pedis and onychomycosis, abdominal wounds that have dehisced secondary to infected seromas, or any of a number of unfortunate breakdowns in integumentary integrity.

Clean or sterile acute wounds can heal by either primary or secondary intention and are relatively straightforward to manage. The fundamentals of that process are the basis for all wound care. In fact, the goal of the management of the chronic infected wound is to modify its conditions to approximate a clean acute wound so as to follow the same uneventful healing process.

Healing of acute wounds involves a cascade of overlapping processes that includes first *hemostasis*, then *inflammation*, followed by *proliferation*, and culminating with *remodeling*. Chronic wounds become chronic when they get stuck in the stage of inflammatory processes because of infection, poor circulation, inadequate enervation, repeated trauma, or some combination of those conditions. The role of dressing selection and wound care management comes down to ameliorating those conditions that impair the progression from inflammation to proliferation.

Wound types can be generally be categorized by their cause, their depth, and their appearance. Causes are almost always multifactorial, but the underlying pathologic process that predisposes a particular patient toward wound development is relevant in the overall care of the wound and the person who hosts it.

Depth is both a physical measurement (in millimeters to centimeters) and a characterization of penetration through the skin and underlying tissues. It is generally divided into *surface*, *partial thickness*, and *full thickness*.

A categorization for pressure ulcers was developed in 1975 by J. D. Shea, then refined and promoted as a tool to promote clear communication between clinicians in 1989 by the National Pressure Ulcer Advisory Panel (NPUAP). In 1997 and 2007, the NPUAP updated their pressure ulcer staging system to reflect the growing understanding of the multifactorial nature of wound development. The following NPUAP definitions are directed specifically at pressure ulcers and do not apply to wounds from other causes (e.g., venous insufficiency, diabetic foot wounds):

**Pressure ulcer:** A localized injury to the skin and/or underlying tissue, usually over a bony prominence, as a result of pressure, or pressure in combination with shear and/or friction.

Stage I: Intact skin with nonblanching redness of a localized area, usually over a bony prominence. Darkly pigmented skin may not have visible blanching; its color may differ from the surrounding area. Note: The area may be painful, firm, soft, warm, or cooler compared with adjacent tissues and may be difficult to detect in individuals with dark skin tones.

Stage II: Partial-thickness loss of dermis presenting as a shallow open ulcer with a red-pink wound bed, without slough. May also present as an intact or open/ruptured serum-filled blister. Note:

Presents as a shiny or dry shallow ulcer without slough or bruising. (Bruising may indicate deep tissue injury; see later discussion.) This stage should *not* be used to describe skin tears, tape burns, perineal dermatitis, maceration, or denudement.

Stage III: Full-thickness tissue loss. Subcutaneous fat may be visible but bone, tendon, or muscle is not exposed. Slough may be present but does not obscure the depth of tissue loss. May include undermining and tunneling. Note: The actual measured depth of the stage III pressure ulcer varies by anatomic location. The bridge of the nose, ear, occiput, and malleolus do not have subcutaneous tissue, and stage III ulcers can be quite shallow. In contrast, extremely deep stage III pressure ulcers can develop in areas of significant adiposity. The key feature is that bone/tendon is neither visible nor palpable.

Stage IV: Full-thickness tissue loss with exposed bone, tendon, or muscle. Slough or eschar may be present on some parts of the wound bed. Often includes undermining and tunneling. Note: As with stage III ulcers, the actual depth varies by anatomic location. Areas without significant subcutaneous tissue (e.g., nose, ear, malleolus) can have very shallow stage IV ulcers, with bone/tendon that is either visible or palpable.

**Unstageable:** Ulcers with full-thickness tissue disruption but with the base of the wound covered by slough and/or eschar are not stageable until the base of the wound is exposed.

#### Types or Healing Stages of Wounds

Acute wounds heal in a relatively orderly and well-organized fashion, with "coordinated actions of both resident and migratory cell populations within the extracellular matrix environment leading to repair of injured tissues." In contrast to this, some wounds fail to heal in a timely and orderly manner, resulting in chronic nonhealing wounds. As mentioned earlier, the usual stages of healing are hemostasis, inflammation, proliferation, and epithelialization.

Chronic wounds are those that fail to progress through the normal stages of healing. Although the most common place for a chronic wound to get "stuck" is in the inflammatory stage, a wound that is exposed to repeated trauma (because of a patient who "picks") can also be functionally chronic. The biologic foundations for the variety of reasons a wound becomes chronic are complex, but the facts that wounds have stages of evolution and that clinical interventions play a role in their development are the obvious motivations behind wound care and dressing selections (Table 44-1).

#### **WOUND BED PREPARATION**

A clean acute wound has, by definition, a prepared wound bed. That is, the injured tissue is disrupted but not necrotic or burdened by

TABLE 44-1 Chronic and Descriptions	Wound Characteristics
Wound Characteristic	Features
Necrotic	Devitalized epidermis Blackened in color Dry and retracted
Sloughy	Containing a layer of viscous, adherent slough Yellow in color Wet Potentially malodorous
Granulating	Significant amounts of highly vascularized granulation tissue Beefy red or deep pink in color
Epithelializing	Evidence of pink margin Isolated pink islands on the surface

foreign bodies or bacterial load. It is ready to start healing and *needs* dressings that simply protect it and keep it on its natural course by preventing it from becoming infected, necrotic, or otherwise healing impaired. This is described further later.

Whether acute or chronic, *a dirty wound* has a wound bed that will not heal well because the inflammatory cascade is upregulated and proliferation of the various cell lines that make up the new tissue (basal cells, fibroblasts, myofibroblasts, and epithelial cells) is inhibited. Thus, the first step in the care of a dirty wound is to *brebare its bed*.

Wound bed preparation means creating an optimal environment for healing with a well-vascularized foundation that is stable and has minimal exudate. This preparation requires reducing the bacterial load, removing necrotic tissue, and optimizing host systemic factors. Bacterial load reduction is achieved through both appropriate systemic antibiotics and selection of a dressing that is bactericidal or at least bacteriostatic.

Dakin's solution and acetic acid solutions have been used for more than a century to decontaminate wounds. There is now clear clinical evidence that these solutions are toxic to fibroblasts and impair healing. However, this does not mean that they do not have a role. Both are extremely effective at reducing the bacterial burden of a wound infected with gram-negative organisms, particularly *Pseudomonas*. Although there is an element of toxicity to polymorphonuclear neutrophils and fibroblasts that slows healing, infection and colonization probably impair healing even more significantly. The judicious course of practice is to make staged use of these solutions as part of 1 to 2 days of wet-to-dry dressing management before converting to a more long-term, tissue-promoting (but less bactericidal) dressing choice.

Virtually all *necrotic tissue requires removal* to develop a healthy wound bed. The notable exception to this rule is the case of dry necrosis without infection. These cases occur under relatively special circumstances of severe frostbite, ischemic injury, and rare other circumstances. Such completely dry necrotic tissue can be *allowed to autoamputate*; however, if the dry necrosis is actually an eschar overlying wet necrosis, intervention is necessary. If there is any indication of infection (i.e., wet necrosis), aggressive débridement is a prerequisite to wound bed preparation and healing.

Débridement can be achieved through progressive dressing changes using a hydrogel and mechanical removal with gauze, surgical/sharp débridement, use of a vacuum device, or, if tolerable, larval therapy (i.e., medical maggots; see Chapter 45, Maggot Treatment for Chronic Ulcers). Under the appropriate conditions, larval therapy is the safest, fastest, and most efficacious method of wound débridement.

As implied earlier, wound bed preparation involves more than simply the local management of the wound. It also requires a perspective that includes the individual patient who harbors the wound. This means thinking about the patient as a whole person and recognizing that the greater milieu of the patient's health state is hugely influential on the outcome of the healing process. Glycemic optimization and nutritional support are often at the foundation of this multidisciplinary approach. A nutritional consult can aid tight glycemic control and suggest if supplementation of key minerals (e.g., zinc) and vitamins (e.g., vitamins A, C, and E) can benefit. Note that although supplementation with zinc in patients with deficiency enhances collagen formation, supplementation with zinc in patients who are *not* deficient can paradoxically cause copper deficiency. Copper deficiency in turn weakens scar tissue through decreased tensile strength. Also, vitamin stores and intake can vary widely depending on individual patient circumstances. Thus, a formal nutrition consult to assess a patient's current and impending status should guide supplementation, rather than wholesale recommendations for general replenishment. Occupational therapy consultation may aid with appropriate bed/chair fitting and selection. In addition, edema should be minimized through compression and elevation, and immunosuppressive drugs such as steroids avoided.

TABLE 44-2 Exa	amples of Antimi	crobial Dressings

#### **DRESSINGS BY DESIGN**

The general objective of all dressings is to promote rapid and cosmetically acceptable healing with minimal patient discomfort. Within this greater expectation, however, dressing types vary greatly in their material composition and primary application. Absorption, infection prevention, infection amelioration, débridement, pain management, and protection are different dressing purposes.

The following describes various dressing types and their characteristics. Each description is followed by a table that includes brand name dressings in each category (where applicable). This section is by no means meant to be an endorsement of any specific product, nor does it claim to be an exhaustive list of products currently available. Nonetheless, it is often difficult for the clinician to recognize based on name or product labeling just what category a given product might fit into. Many health care organizations do not stock the entire line of a given supplier's products, and how to mix and match what is available at an institution to address the progressive dressing needs of a given wound can be very confusing. The purpose of the tables is to provide a basis for this sort of cross-reference.

#### **Dressing Types and Characteristics**

#### **Antimicrobial**

Antimicrobial dressings are used for locally infected or colonized wounds to reduce the microbiologic load (Table 44-2). Solutions of acetic acid or dilute bleach (Dakin's solution) have been used for years for this purpose but except in specific and judicious applications should be replaced with the less host-toxic options now available. Dressings made with silver, in ionic or nanocrystalline form, have been demonstrated to be very effective antimicrobials with bactericidal rather than just bacteriostatic qualities. Silver dressings include both silver-infused creams and meshes (Figs. 44-1 and 44-2).

Iodine is an excellent bacteria eradicator, but in some forms it has been clearly demonstrated to delay healing. Povidone-iodine

**Figure 44-1** Acticoat, a silver-impregnated antimicrobial barrier dressing. (Courtesy of Smith & Nephew, St. Petersburg, Fla.)

**Figure 44-2** Iodine-containing products. **A,** Iodosorb cream. **B,** Iodoflex mesh. (Courtesy of Smith & Nephew, St. Petersburg, Fla.)

(Betadine) in particular has been implicated as more toxic than others for overall healing in spite of its efficacy against bacterial infection and colonization. It remains an extremely effective preoperative skin preparation agent but should not be used directly in open wounds. There are, however, other iodine-based dressings that are indicated for wound care (see Fig. 44-2). For patients with thyroid disease, caution needs to be maintained and thyroid function monitored because it has been demonstrated that there is systemic uptake of iodine through dressings.

Other *antibiotic ointments and creams* are useful in that they create a barrier to prevent new infection and can reduce the risk of cross-colonization with other wounds or uninfected tissues. Ointments or creams can be used directly on or over a wound and be subsequently covered with a dry gauze or bandage to form a basic antibacterial dressing.

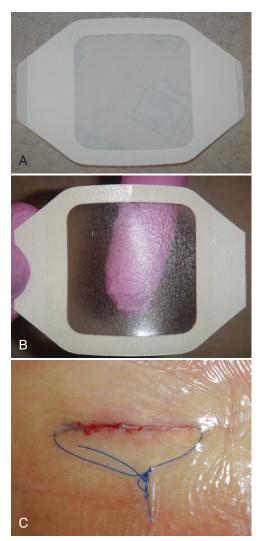

#### Low-Adherent and Nonadherent

Low-adherent and nonadherent dressings are designed to reduce their adherence to the wound bed and either permit (hydrophilic) or prevent (hydrophobic) drainage of fluid from the wound (Table 44-3). The hydrophobic low-adherent and nonadherent dressings thus are also a form of occlusive dressing. The hydrophilic dressings are designed to be used with an overlying absorptive dressing that is in turn usually occlusive (e.g., a foam or gel dressing). Most of these are in the form of tulles, textiles, or multilayered or perforated plastic films.

#### Semipermeable

Semipermeable films consist of transparent polyurethane sheets that are coated with hypoallergenic acrylic adhesives. They promote a moist environment by occluding the wound, adhere to the healthy skin

TABLE 44-3 Low-Adherent and No Dressings	onadherent
Hydrophilic	Hydrophobic
Adaptic (Johnson & Johnson, New Brunswick, NJ) Xeroflo (Kendall, Ltd.) Mepitel (Mölnlycke Health Care, Norcross, Ga) Tegapore (3M, St. Paul, Minn) N-Terface (Winfield Labs, Richardson, Tex) Fine-mesh gauze or chiffon (not a brand, but a type of cloth)	Vaseline Gauze (Kendall, Ltd., Mansfield, Mass) Xeroform (Kendall, Ltd.) Telfa (Kendall, Ltd.) Scarlet Red Ointment Dressing (Kendall, Ltd.)

**Figure 44-3** Tegaderm, a hydrophobic low-adherent dressing. **A,** The dressing with the protective backing in place. **B,** The protective backing has been removed, leaving a transparent window for proper application. **C,** Tegaderm placed over a recently closed excision (subcuticular running closure). (but not wound), and allow visualization of the wound and surroundings skin (Fig. 44-3). However, because they are just a film over the wound, they do not provide any padding, nor do they address the amount of exudate an infected wound often produces (Box 44-1). Thus they are most suitable for flat, shallow wounds with low exudates, or for use as a secondary dressing (i.e., in lieu of tape covering dry gauze to create an occlusive dressing). These dressings

## Box 44-1. Examples of Semipermeable Film Dressings

Bioclusive (Johnson & Johnson, New Brunswick, NJ) CarraFilm (Carrington, Irvine, Tex) Mefilm (Mölnlycke Health Care, Norcross, Ga) OpSite Flexigrid & OpSite Plus (Smith & Nephew, St. Petersburg, Fla) Tegaderm (3M, St. Paul, Minn)

#### Box 44-2. Examples of Hydrocolloid Dressings

Comfeel (Coloplast, Humlebaek, Denmark)
Cutinova (Smith & Nephew, St. Petersburg, Fla)
DuoDerm (ConvaTec, Princeton NJ)

NuDerm (Johnson & Johnson, New Brunswick, NJ)
Tegasorb (3M, St. Paul, Minn)

are often used over sutured wounds not only to provide protection and moist healing, but to decrease the tension on wound margins. Care is minimal because these covered wounds can become wet (e.g., bathing) without consequence.

#### Hydrocolloids

Hydrocolloids are a class of nonbiologic occlusive dressings that contain a hydrocolloid matrix composed of carboxymethylcellulose, gelatin, elastomers, and pectin on an adhesive sheet or wafer, or as a paste or powder. Although their forms vary by brand and type, the hydrocolloid dressings have in common that they form a gel on contact with wound exudates (Box 44-2). Although there is little clinical evidence based on randomized, controlled trials to guide dressing choices generally, it has been fairly well established that hydrocolloids are more effective than either paraffin gauze or wetto-dry gauze dressings.

Hydrogels are a matrix of insoluble polymers, usually sodium carboxymethylcellulose, modified starch, or sodium alginate, that are partially hydrogenated and able to simultaneously donate water molecules to the wound surface (maintaining moistness) and absorb some wound exudates. They are the standard for management of sloughing or necrotic wounds. They promote wound débridement by rehydration of nonviable tissue, thus encouraging autolysis (Fig. 44-4). All hydrogels may be left in place for multiple days but require a secondary dressing overlying them. For very dry wounds, the secondary dressing should be occlusive, such as a semipermeable film (Box 44-3).

#### Box 44-3. Examples of Hydrogel Dressings

GranuGel (ConvaTec, Princeton, NJ) Intrasite (Smith & Nephew, St. Petersburg, Fla) Nu-Gel (Johnson & Johnson, New Brunswick, NJ) Purilon (Coloplast, Humlebaek, Denmark) Tegagel (3M, St. Paul, Minn) Vigilon (Bard, Murray Hill, NJ)

#### **Alginates**

Alginates are made of the calcium and sodium salts of alginic acid, found in a class of brown seaweed (Phaeophyceae). Commercially produced alginates are either 100% calcium alginate or a combination of calcium with sodium alginate at a ratio of 80:20 (Box 44-4). The alginates, like the hydrocolloids, react on contact with the wound exudate to form a gel. Typically, they can absorb 15 to 20 times their weight of fluid and are excellent choices for highly exudative wounds. They should not be used in wounds with little exudate because they will dry out the wound surface, adhere to it, and cause pain on removal. With respect to removal, alginates need to be changed daily and to have a secondary dressing overlying them (i.e., gauze or film; Fig. 44-5). Those with higher concentrations of mannuronic acid (e.g., Kaltostat) can be washed off with saline, whereas those higher in guluronic acid (e.g., Sorbsan) will retain their structure and can be removed as a single piece.

#### Foam Dressings

Foam dressings are manufactured from either a polyurethane or silicone foam and are available as sheets (with and without integrated adhesives) or cavity-filling chips. Foam dressings are excellent for absorbing large amounts of exudates, provide a level of protection in the form of padding, and are generally occlusive, thus not requiring additional overlying dressing. Furthermore, under most circumstances, they may be left in place for 2 to 3 days at a time, reducing the cost and discomfort of frequent dressing changes (Table 44-4 and Fig. 44-6).

#### **Vacuum Dressings**

A vacuum dressing is a mechanical device that uses a reticulated foam dressing cut to the shape of the individual wound and then covered by an occlusive drape through which a sealed vacuum tube is placed. The tube is connected to a pump, which provides 50 to 125 mm Hg of negative pressure to the wound environment (Figs. 44-7 and 44-8). The technology is available through KCI Medical (San Antonio, Tex). The KCI V.A.C. device has been demonstrated to enhance local blood flow, diminish edema, limit bacterial proliferation, and accelerate granulation tissue formation. It has excellent capacity to remove drainage and exudates and acts as an effective débridement tool. Indications for using a KCI V.A.C. include chronic open wounds, dehisced incisions, meshed grafts, and flaps, as well as either chronic or acute traumatic wounds. Contraindications to its use are fistulas to organs or internal cavities, necrotic

tissue in eschar, untreated osteomyelitis, and malignancy in the wound.

#### **General Recommendations**

Among the review articles and other published works on wound management from the past 15 years, there is a consensus statement by experts published in 2007 (Vaneau and colleagues, 2007). A steering committee selected a panel of 27 experts who had no declared conflicts of interest; they worked first from questionnaires, then discussion, followed by working-group peer review. Their recommendations are given here regarding the application of specific dressing types for specific wound stages:

- Acute wounds, epithelialization stage (i.e., postoperative): Lowadherent dressings
- Epithelialization stage: Hydrocolloid and low-adherent dressings
- Débridement stage: Hydrogels
- Granulation stage: Foam and low-adherent dressings
- Hemorrhagic wounds: Alginates (effective both for absorption of exudates and hemostasis)
- Malodorous wounds: Activated charcoal; metronidazole gel (good for anaerobic bacteria)

It should be noted, however, that a paucity of published evidence based on actual trials limits these recommendations. In particular, firm conclusions could be drawn on only three types of dressings (hydrocolloid, alginate, and foam dressings), and the committee made no comment one way or the other on either surgical/sharp

débridement techniques or larval therapy (maggots) as methodologies for removal of necrotic tissue from wounds.

Other criteria that were agreed on as useful for individual clinicians' decision making but for which there was insufficient evidence to make specific recommendations included the following:

- Pain or discomfort on application and removal
- Management of exudates
- General dressing tolerance (e.g., ability of caregiver/nursing staff and patient to accept larval therapy)

#### **Dressings for Specific Wound Types**

Table 44-5 and Box 44-5 present general recommendations for types of dressings based on wound types and the healing objective of the dressing.

## OTHER CONSIDERATIONS IN WOUND MANAGEMENT AND DRESSING APPLICATION

One of the most common problems in wound management is failure to protect the surrounding healthy skin or tissue and resultant expansion of the wound area. Although much of this discussion has focused on dressing choices that take the clinician away from traditional wet to dry gauze dressings, these outdated techniques nonethe-

Figure 44-7 V.A.C. dressing in place in knee wound.

**Figure 44-8** V.A.C. dressing in sacral wound, with adjacent wound before second dressing has been placed.

less remain one of the most common choices (familiarity and lack of knowledge about other choices being the most likely reasons for this). A common error made by many nurses, physicians, and other caregivers who change dressings is that of allowing wet material to macerate dry, intact skin. This can be a problem with any dressing that either does not keep up with absorption of exudates or is oversized and sits on intact skin. For areas that are constantly exposed to moisture, a layer of hydrophobic ointment or thick cream (e.g., zinc oxide, A&E ointment, or Desitin cream) can prevent maceration and further breakdown of the skin.

Of additional concern, the dry, intact skin surrounding a wound is exposed to the adhesives of the binding layer of the dressing (i.e.,

## TABLE 44-5 Dressing Recommendations Based on Wound Type and Dressing Objectives

on Wound ly	pe and Dressing C	Objectives
Wound Type	Dressing Objective	Dressing Recommendation
Incisional/Surgical wounds	Protect wound from contamination Immobilize wound edges Compression	Benzoin + Steri-Strips Antibacterial ointment Low-adherent dressing Semipermeable film
Skin tears	Protect wound from contamination Immobilize wound edges	Antibacterial ointment Low adherent dressing Semipermeable film
Partial-thickness wounds or donor sites	Facilitate epithelialization Absorb exudate Protect wound from contamination	Low-adherent dressing + overlying absorptive layer (foam or gauze) Antibiotic cream/ointment + gauze or foam Occlusive dressing with absorptive property (hydrocolloid sheets or foam dressing)
Full-thickness wounds (pressure wounds, surgical site dehiscence, third-degree burns)	Maintain moisture Absorb exudate Débridement	Hydrogels Alginates Foam dressings KCI V.A.C. dressing
Any wound with heavy load of necrotic tissue	Absorb exudate Débridement	Larval therapy/dressing KCI V.A.C. dressing
Malignant wound	Maintain moisture Absorb exudate Odor control	Foam dressings for absorption Metronidazole gel Activated charcoal (Actisorb Plus or Lyofoam C)

plastic or paper tapes, Coban, clear occlusive dressing), which can cause skin tears and irritation such as blisters and rash. Care should be taken to protect intact skin by using a skin protectant, either a thin liquid applied and dried or even a thin film dressing (e.g., Tegaderm or Op-Site), on areas of intact skin that are repeatedly exposed to adhesives and the mechanical irritation of their repeated removal and reapplication.

In addition to the general wound types most frequently encountered (e.g., pressure ulcers, venous stasis ulcers, nonhealing infected surgical wounds), the clinician will occasionally have to address the recalcitrant and fungating *malignant wound of neoplasia*. These wounds may need to be addressed somewhat differently because their management objective may not be actual healing. Rather, the objective may be to maintain quality of life for the patient, who must live with the open wound for the remainder of his or her life. Thus, *management of odor* and *appearance* is of greater import than achieving resolution of the wound site. Activated charcoal can reduce unpleasant odors and is found in dressings such as ActiSorb and Lyofoam Plus.

Wounds containing toxins, such as those produced by brown recluse spider bites or infiltrated chemotherapeutic agents, are also treated differently in that they require aggressive, usually wide surgical débridement to remove the offending agent and limit ongoing damage to tissue.

#### **SUMMARY AND RESOURCE REFERENCES**

Wound management is a challenging element of patient care that requires a multidisciplinary approach for optimization of the final outcome. It is incumbent on the clinician(s) to be willing to change course as the wound's character evolves. Dressing selection is a vital and dynamic, but not singular, element of the total wound care. No amount of dressing expertise can overcome the deleterious effects of ignoring the patient's condition as a whole—medical, metabolic, social, and emotional states are crucial for healing in the global sense.

#### **CPT/BILLING CODES**

Procedures 16000 to 16030 refer to local treatment of burned surface only.

- 11000 Eczema/infected skin—first 10%
- 11001 Eczema/infected skin—each additional 10%
- 11040 Débridement partial-thickness skin
- 11041 Débridement full-thickness skin
- 11042 Débridement skin and subcutaneous tissue
- 11043 Débridement skin, subcutaneous tissue, and muscle
- 11044 Débridement skin, muscle, bone
- 15852 Dressing change (for other than burns) under anesthesia (other than local)
- 16000 Initial treatment, first-degree burn, when no more than local treatment is required
- 16010 Dressing/débridement, initial or subsequent, under anesthesia, small
  - 16015 Under anesthesia, medium or large, or with major débridement
  - 16020 Without anesthesia, office or hospital, small
  - 16025 Without anesthesia, medium (e.g., whole face or whole extremity)
  - 16030 Without anesthesia, large (e.g., more than one extremity)

## MAGGOT TREATMENT FOR CHRONIC ULCERS

Kim Haglund • Marisha Chilcott

Pressure ulcers and other types of chronic wounds are commonly encountered by primary care providers, especially those who provide care for nursing home residents. Getting such wounds to heal can be a daunting task and requires attention not only to optimal wound dressings but to pressure relief measures, nutrition, and hygiene. The first step toward wound healing is to remove necrotic tissue from the wound and create a clean wound base. Necrotic tissue removal may be accomplished by surgical débridement, either in the operating room or at the bedside; chemical débridement with products that soften or liquefy dry necrotic tissue; or mechanical débridement, such as traditional "wet-to-dry" gauze dressings that pull adherent necrotic tissue from the wound bed when the gauze packing is removed. Although all of these methods have a role in chronic wound management, they all have some disadvantages. Each method can cause damage to adjacent viable tissue and can be uncomfortable for the patient. Surgical débridement in the operating room also exposes the patient, who may have multiple comorbidities, to the risks of anesthesia. Maggot débridement, on the other hand, has the advantages of not harming viable tissue, débriding accurately and completely even in areas of undermining or tunneling, and, in our experience, being very well tolerated in terms of patient comfort.

#### **INDICATIONS**

- Maggot therapy is indicated for débridement of soft tissue wounds with any type of devitalized tissue in the wound area, including dry eschar, densely adherent fibrinous exudates, or purulent exudates.
- Maggot therapy works well for pressure ulcers, venous stasis ulcers, neuropathic foot ulcers, and nonhealing traumatic or surgical wounds.

## RELATIVE AND ABSOLUTE CONTRAINDICATIONS

- Maggot therapy does not work very well for ischemic wounds because the maggots may débride tissue from the wound edges that, although not visibly necrotic, is not really viable owing to very poor perfusion, thereby enlarging the wound area. Such wounds should be treated first with revascularization; once good perfusion is restored, maggots may be used if needed.
- Wounds such as fistulas that communicate with internal organs or body cavities should never be treated with maggots.
- Wounds that are manifestations of an acute life- or limbthreatening infection.
- Allergy to brewer's yeast or soy protein (both used to grow the larvae).
- Allergy to the blowfly larvae.

 Bleeding from the wound bed is common during maggot débridement and, in patients on anticoagulation or with a coagulopathy, may be severe enough to require stopping therapy. Caution should be exercised when deciding whether to use maggot therapy for a patient on anticoagulation or with a coagulopathy.

#### **EQUIPMENT AND SUPPLIES**

To make a maggot dressing, you will need the following:

- Medical-grade maggots. In the United States, order from Monarch Labs (the only U.S. supplier of maggots for medical use; Fig. 45-1). Vial cost for 250 to 500 larvae is approximately \$90 (2008 fee), with overnight shipping \$39 to \$47 additional. They should be used within 24 hours of receipt.
- "Cage" material, either Dacron chiffon (order from Monarch) or other small-pore fabric. We have used cut-up Ted hose with good results when Dacron was unavailable. Monarch will also provide custom-cut pieces of Dacron if you need a bigger piece. The Monarch website states that nylon stockings can be used, but you must select stockings with a weave that is tight enough to prevent the maggots from escaping when they are still small.
- Hydrocolloid dressing to protect skin around wound (not essential).
- Protective skin prep solution.
- Adhesive solution (e.g., benzoin).
- Saline solution.
- Dry gauze.
- Tape.
- Cotton-tipped applicators.
- Two plastic (red, biohazard) trash bags for disposal.
- Ethyl chloride.

#### PREPROCEDURE PATIENT EDUCATION

Maggot therapy is not well known to the general public or even to many nurses or physicians. Thus, when instituting maggot treatment, it is important for the provider to demystify the procedure and remove the "yuck" factor as much as possible. Try to stress to patients that maggots work like tiny, flexible, and mobile surgical instruments to remove dead or infected tissue from tight corners or tunnels under the skin where human hands and instruments cannot reach. For patients who may be living in a long-term care facility, let the family know when and why maggot therapy is planned because they may misinterpret maggots in the wound as a sign of neglect. See the patient education form available online at www. expertconsult.com.

Figure 45-1 Vial of medical-grade maggots.

#### **TECHNIQUE**

#### **Application of Maggots**

- 1. Before starting, check the viability of the maggots—you should be able to see them crawling along the walls of the vial. If none are moving, make sure the vial is warm (room temperature at least). If still no movement after warming, contact Monarch Labs for a replacement.
- 2. Apply protective skin prep solution to intact skin around wound.
- 3. Cut a donut of hydrocolloid dressing to fit around the wound. (This step is not strictly necessary, but does protect vulnerable skin and allows the application of potentially irritating adhesive to the dressing rather than directly to skin.) The hole needs to match the wound in size and shape, leaving 2 to 3 cm of hydrocolloid margin around the wound (Fig. 45-2).
- 4. Apply the hydrocolloid donut to the skin, making sure it sticks securely and has no wrinkles.
- Apply a layer of adhesive (benzoin works well) to the top surface of the hydrocolloid. If hydrocolloid is not being used, apply the adhesive to the prepared skin.

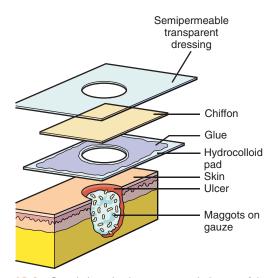

Figure 45-2 Cut a hole in the dressing to match the size of the wound. Typical layering of materials when using maggot therapy.

Figure 45-3 Ulcer prepared for medical maggot treatment.

- 6. With an open plastic trash bag tucked under the body part to which the maggots are being applied (to catch "runaways" and make cleanup easy), open the vial of maggots and gently use cotton-tipped applicators to nudge them into the wound bed. The recommended dose of maggots is five to eight maggots per square centimeter of wound area. For wounds larger than 5 × 5 cm, simply use the whole vial. The piece of damp gauze that comes in the vial may be used to gently wipe the maggots from the sides of the vial (many more will already be burrowed into the gauze itself) and then apply them to the wound. The gauze is then placed in the wound bed. The maggots tend to collect on the underside of the vial lid and in the crevice of the lid, so bang the vial against a hard surface before beginning to knock them to the bottom of the vial. If you are having trouble getting them out, an easy way is to pour a little saline in the vial, swirl, and pour out onto a gauze pad. Then put the damp gauze and maggots into the wound.
- 7. Once the maggots are in place, apply a little damp, loosely fluffed gauze to cover them and keep the wound bed moist.
- 8. Apply the Dacron or other fabric "cage" over the wound, sticking it to the prepared hydrocolloid while being careful to avoid wrinkles. Wrinkles create tunnels through which maggots can escape. The edges of the fabric can be taped to the skin or hydrocolloid for an extra measure of security.
- 9. Put a few squares of dry gauze on top of the fabric cage to absorb drainage, then secure with tape. Do not use too thick a pad of dry gauze or the maggots will be smothered. This dry dressing should be changed as often as needed, usually a few times a day. Although there may be substantial drainage, avoid the temptation to use an abdominal pad or other occlusive absorbent material because you will find that the maggots do not tolerate the lack of oxygen (Figs. 45-3 and 45-4).
- 10. When the maggots are secured in place, the patient may lie on the wound without concern for killing the maggots.
- 11. Put all maggot-related trash in plastic bag, double-bag, and dispose. You cannot save maggots for future use if you do not use them all.
- 12. Remove maggots (see next section) in 2 to 3 days and reapply new maggots with a fresh "cage" and dressings if débridement is incomplete.

#### Removal of Maggots

- 1. Place a biohazard plastic bag under the body part to be débrided.
- 2. Remove the dry gauze, fabric cage, and damp gauze from the wound bed and place in the trash bag. The damp gauze will have lots of maggots crawling in it. They should be much bigger than

Figure 45-4 Ulcer dressed with medical maggots in place.

when applied—at least the size of grains of cooked rice—but there may seem to be many fewer because some may have died.

- 3. If there is any undermining or tunneling of the skin, maggots likely are in these spaces. Probe into tunnels with cotton-tipped applicators, wipe the wound with gauze, or flood the wound with saline to flush them out.
- 4. If you think there may be maggots left behind, apply a damp gauze dressing to the wound bed, cover with a fabric cage, and secure as for a regular maggot dressing. The maggots will stop eating when they are full and will migrate out of the wound and into the gauze. There is no danger of them eating healthy tissue even if all the necrotic tissue has been removed—they will simply migrate out of the wound and "hide" in the gauze. Change the gauze three or four times a day for a day or two and all the maggots should be gone.
- 5. Even if you are sure all the maggots appear to be gone, damp-to-dry gauze dressing changes should be made three to four times daily for 1 to 2 days between cycles of maggot therapy. This helps remove any material that has been liquefied by the maggots but not consumed.
- Reapply a new vial of maggots 1 to 2 days after removal of the first set. Most wounds require only two or three cycles of maggot treatment. Very large wounds may need up to five or six treatments.
- 7. The hydrocolloid donut may be left in place for up to 1 week through multiple cycles as long as it is still adhering well and the skin beneath does not appear macerated.
- 8. If maggots are escaping from the trash bag while you are trying to remove them from the wound bed, they can be sprayed with ethyl chloride to slow them down.

Once the maggots have débrided all of the necrotic tissue and a clean wound bed is present, the wound will heal by secondary intention. The débrided wound may be left open or may be covered with a usual dressing to maintain a clean, moist wound environment

Once maggots have died, they should be removed. Otherwise, they may trigger an allergic response or become a catalyst for further infection.

#### **COMMON DIFFICULTIES**

- Escaped maggots due to wrinkles in cage material or tape.
   Resolution: Make sure the material is flat when laid down on the adhesive and take care with taping. Multiple pieces of flat tape are better than a few pieces with wrinkles or folds.
- Dead maggots when dressing removed.
   Resolution: Make sure the gauze dressing over the maggots is not too occlusive or too dry. Maggots need plenty of oxygen and a moist environment.

 Maggots escaping through the cage despite it being adequately secured around the edges.

We have only had this problem when using nylon stockings to cover leg wounds, never with the Dacron chiffon pieces supplied by Monarch. Use the Dacron or a tightly woven stretch fabric (TED hose works) rather than ordinary pantyhose.

#### **COMPLICATIONS**

The most serious potential complication is *bleeding*. Although most wounds will have mild oozing from a healthy granulating base once the maggots have débrided off necrotic tissue, rarely will there be such heavy bleeding that maggot therapy will have to be abandoned. If the wound includes necrotic tissue through which blood vessels course, maggot débridement may also cause significant bleeding by débriding away the vessel wall. If this happens, the bleeding vessel will need to be controlled with a figure-of-eight stitch, or cautery if the vessel is small enough.

Maggots can also cause *pain or discomfort*. This usually occurs at 24 to 36 hours into therapy and increases as larvae grow larger. If analgesics do not help, remove the dressing, which generally affords immediate relief. Do not apply local anesthetics.

#### **BILLING AND CODING**

Medicare/Medicaid and most insurance companies will cover maggot therapy. If a patient is uninsured or his or her insurance does not cover maggots, there is a Patient Assistance Grant program offered through BTER Foundation (BioTherapeutics Education and Research Foundation) that will cover the cost of the maggots. See the BTER website or the Monarch Labs website for more information.

#### **CPT/BILLING CODES**

ABC code for Maggots (EAACT) or HCPCS misc code A9270.

97597 For wounds 20 cm<sup>2</sup> or less 97598 For wounds greater than 20 cm<sup>2</sup>

#### **ICD-9 DIAGNOSTIC CODES**

707.00 For decubitus ulcer (and gangrene) with following locations

707.01 Elbow

707.02 Upper back, shoulder blades

707.03 Lower back, sacrum

707.04 Hip

707.05 Buttock

707.06 Ankle

707.07 Heel

707.09 Head, other sites

879.8 Wound, skin, complicated NEC

If reimbursement is denied, appeal. The BTER Foundation will assist with appeals as well as provide Patient Assistance Grants.

## Introduction to Aesthetic Medicine

Haneef Alibhai

As our world continues to evolve, investment in health and wellness is now, more than ever, a top priority for people living longer, healthier, and more active lives. With this comes an ever-growing demand for various surgical and nonsurgical cosmetic medical procedures to enhance one's appearance and overall wellness.

In 2008, over 10 million cosmetic medical procedures were performed in the United States. Eighty-three percent of these procedures were nonsurgical (American Society of Aesthetic Plastic Surgeons). Since 1997, surgical procedures increased by 80% and nonsurgical procedures increased by 233%. Ninety-two percent of the procedures were preformed on women. The top five nonsurgical cosmetic procedures in 2008 were botulinum toxin (Botox) injections (2,464,123 procedures), laser hair removal (1,280,964 procedures), hyaluronic acid dermal filler treatments (1,262,848 procedures), chemical peels (591,808 procedures), and laser skin resurfacing (570,880 procedures). The most popular procedure among people younger than 35 years of age was laser hair removal, whereas the most popular procedure among people older than 35 years was botulinum toxin injections. In 2008, Americans spent almost \$11.8 billion on cosmetic procedures.

#### **AGING POPULATION**

Currently, baby boomers—born between 1946 and 1964—are the most powerful consumers in the world of aesthetic and cosmetic treatments, with more each year spending millions on cosmetic and aesthetic procedures. In the United States, baby boomers now make up 51% of the total population, with 12,000 people turning 50 every day (one every 8 seconds). This trend will continue, with the number of Americans older than 55 years growing by 60% in the next 20 years.

#### **FACIAL AGING PROCESS**

As we age, our skin matures (chronologic aging). This is generally accelerated because of a process known as *photo-aging*. Photo-aging refers to premature aging from sun exposure, smoking, and genetic predisposition. *Healthy skin* is defined as skin that is smooth, firm, glowing, clear of blemishes and vascular lesions, and plump with natural moisture. *Unhealthy skin* is defined as skin that is uneven, blotchy with pigmentation, poor in tone and elasticity (thin), leathery, dull, and covered with age spots, telangiectases, fine lines, and wrinkles. These unwelcome changes are brought about by the pull of gravity and the cumulative damage to DNA, collagen, and cell membranes by free radicals produced from normal cellular metabolism, environmental elements, and sun exposure. (Also see the discussion of aging skin in Chapter 59, Skin Peels.)

For centuries, we have strived to slow down the aging process in an attempt to look and feel younger. The facial rejuvenation process aims to achieve the following goals.

- Reverse sun damage and reduce the signs of aging (vascular and pigmented lesions)
- Renew and retrain skin cells to appear younger and function more effectively to maintain youthful appearance (smooth skin)
- Relax overactive muscles that cause wrinkles
- Replace lost volume
- Tighten sagging and loose skin
- Stimulate dermal collagen production

During the past decade, much progress has been made in the field of noninvasive facial rejuvenation. The list of noninvasive facial rejuvenation techniques has grown considerably in response to the aging baby boomer's demand for procedures that combine safety, efficacy, predictability, and, of course, minimal downtime. The following noninvasive facial rejuvenation techniques are the most widely performed and sought-after procedures:

- Cosmeceutical skin care
- Microdermabrasion and dermal infusion
- Chemical peels
- Photofacial rejuvenation (intense pulsed light, or IPL)
- Laser/IPL treatment of hair, veins, pigmented lesions, acne, and tattoos
- Ablative laser resurfacing (carbon dioxide, erbium:yttriumaluminum garnet)
- Light-based therapies (e.g., radiofrequency [RF], light-emitting diode [LED] photomodulation, infrared [IR] devices, fractional resurfacing)
- Nonablative/fractional skin resurfacing
- Nonablative/fractional skin tightening (RF, IR)
- Ablative/fractional skin resurfacing
- Photodynamic therapy (PDT)
- Sclerotherapy
- Botulinum toxin injections
- Dermal filler treatments

Even more recently, cosmetic physicians have begun combining rejuvenation techniques in an attempt to provide better and longer-lasting results. Depending on the patient's concerns and goals, most facial rejuvenation procedures can be performed in concert to provide patients with excellent, long-lasting results. Indeed, when combined, these procedures offer far superior results compared with the results from any single procedure.

Without question, aesthetic medicine is the most exciting and rapidly growing field of medicine today. Given this staggering growth, it is more important than ever for providers to constantly seek education opportunities to keep up to date with recent advances in technology and new procedures in aesthetic medicine. This section of the text provides an overview of the most popular and sought-after cosmetic rejuvenation procedures available today. Those who want to enter the field of aesthetic medicine are strongly

encouraged to undergo intensive hands-on clinical training with an experienced aesthetic physician.

### INITIAL COSMETIC AND AESTHETIC ASSESSMENT VISIT

Regardless of the reason for the initial visit, it is essential that a full evaluation be made of the *overall health status*. The general health history questionnaire can be used for an overview, but specific questions should then be asked about the skin (Fig. 46-1). It is important to determine exactly what it is the patient is concerned about because another procedure may be more appropriate than what the patient has requested.

For light-based therapies, determining the Fitzpatrick skin type (see Chapter 48, Lasers and Pulsed-Light Devices: Hair Removal, section on "Fitzpatrick Skin Types and Treatment Implications" and Fig. 48-7) is important because the amount of energy needed will vary depending on the skin type.

It is also important to determine if there has been recent use (within 6 months) of isotretinoin (Accutane) because it markedly increases the skin's sensitivity to light and many other products.

If the patient has a history of *herpes simplex*, it may be wise to use antiviral prophylaxis to prevent an outbreak if generalized facial procedures like ablative laser resurfacing or more aggressive peels are to be performed (e.g., valacyclovir [Valtrex] 2 g immediately, followed by 2 g 12 hours later).

Understanding what the patient has used for skin care and what is available to improve the appearance of the skin is very helpful (see Chapter 47, Cosmeceuticals and Skin Care).

Effective topical anesthetics are beneficial for many procedures. Care must be taken that they be used appropriately, especially if applied under occlusion, because side effects can be significant (see Chapter 5, Local and Topical Anesthetic Complications, and Chapter 10, Topical Anesthesia). In some instances, an anxiolytic (e.g., diazepam [Valium] 10 mg 30 minutes before the procedure) will make the experience easier (e.g., ablative laser resurfacing).

This initial visit not only allows a comprehensive evaluation of the patient, it allows the provider to assess the patient's psychological makeup. An honest discussion of findings is essential. Conditions such as body dysmorphic syndrome should be recognized and dealt with in a straightforward fashion lest the patient be harmed further. The main objective of the initial consultation is to educate the patient on the various nonsurgical cosmetic procedures that are available. The discussion focuses on the procedures deemed to be most appropriate for the patient. Based on the patient's concerns, timeline, goals, and budget, a customized treatment plan will be developed (Fig. 46-2). It is imperative that realistic expectations be set when discussing outcomes. Experience over the years has proved that it is best to be honest with patients and to "under-promise and over-deliver."

#### **BEFORE AND AFTER PHOTOGRAPHS\***

Obtaining before and after photographs can be very beneficial in an aesthetic practice and is strongly recommended. Photographs document the appearance before an intervention for both the patient and the provider. Patients frequently "forget" their initial appearance and see only what remains to be done. Having a "before" photograph can document the changes. Physicians can also use the photographs to gauge what interventions have had the most impact over time.

#### **General Tips**

 Ideally, all photographs should be taken in a designated room using a blue background.

- Lighting, distance, background, and views taken should be duplicated for both the before and the after photographs.
- Additional background options: dark solid wall color, posterboard, felt, blue window shade mounted on the back of a door.
- Limited or no jewelry for both before and after photographs.
- Hair pulled away from the face.
- Views should be consistent: full face/oblique/profile/close-up of treatment area.

#### "Before" Tips

- The "before" photograph should be taken during the initial consultation, before any treatment.
- If face has not been cleansed, use a makeup remover wipe to remove the majority of makeup.

#### "After" Tips

- "After" photographs should be as similar as possible to the "before" photograph.
  - If no makeup is worn in the "before" (recommended), the "after" also should be taken without makeup.
- "After" photographs should be taken at predetermined time frames.
  - Example: 7 to 10 days postpeel, and again at 3, 6, 9, and 12 months

#### Preparing for the Photograph

- Take a photograph of the name on the chart before taking a photograph of the patient.
- Adequate lighting: If the picture is taken with a digital camera, the photograph should not have a yellow hue.
- For dermal filler photographs, turn the flash off: When using a digital camera, the flash washes out folds.
- Date stamp: Turned on for recording the date the photograph is taken.
- Stool with no back.
  - Patient should be sitting up straight and not leaning back against anything.
  - Position stool approximately 1 foot from the wall; check viewfinder for shadows.
  - Pull hair back away from the face and remove all or large iewelry.

#### Taking the Photo

- Head position
  - The *ala-tragus line should be parallel to the floor* (the ala-tragus line is an imaginary line that runs from the nostril to the cartilaginous projection in the middle of the ear).
  - Another way to check head position is to be sure the occlusal (biting) surface of the teeth is parallel to the floor.

#### **Full-Face Photo**

- Have the patient sit up straight.
- Head position: straight, ear not tipped toward either shoulder.
- Hair away from jaw line.
- Eyes open and focused straight ahead, not looking up or down.
- For "blinkers"—keep the eyes closed until you have the view in focus, then open eyes.

#### **Additional Checks**

- Ala-tragus line or occlusal surface parallel to the floor.
- Chin not tipped too far up or down.
- Lips in a neutral position—not smiling or frowning.
- Head should take up entire frame—do not crop off hair or chin.

**Figure 46-2** Customized Aesthetic Treatment Plan form.

#### **Oblique View and Profile Views**

- Repeat aforementioned positioning checks.
- Rotate the stool, not just the person's head.

#### **PATIENT EDUCATION AND CONSENT**

Probably more than in any other area of medicine, the time must be taken to evaluate the patient's condition and wishes. A frank discussion of risks, benefits, possible complications, alternative therapies, and expected outcomes is essential. It is important not to "oversell" a procedure (see consent forms online at www.expertconsult.com). Educational handouts explaining the procedure; before, during, and after photographs from previous patients; and written postprocedure instructions can be very helpful. The majority of the procedures in this section are elective, and it is essential that patients have realistic expectations of what can be accomplished.

Aesthetic medicine can be a very enjoyable and rewarding area in which to practice. The key to success is combination therapy because no single procedure will address all of the concerns that may bring a patient to a cosmetic clinic. Physicians must therefore be well trained and seek continuing education as this field continues to grow so rapidly. Ultimately, honest communication, patient education, outstanding customer service, and ethical care are the cornerstones of success in aesthetic medicine.

# COSMECEUTICALS AND SKIN CARE

Wendy L. Smeltzer

Products applied to the skin can range from purely cosmetic products to prescription drugs, but many fall somewhere in between and are commonly referred to as cosmeceutical agents. The term cosmeceutical is widely used in the skin care industry but is still not recognized by many regulatory bodies such as the U.S. Food and Drug Administration (FDA). However, cosmeceuticals are a reality, as evidenced by the widespread use of this term and a growing number of textbooks and symposia in the medical aesthetics field on this subject. The share of the skin care market comprising cosmeceuticals continues to grow and is the fastest-growing segment of skin care products in the marketplace.

#### **DEFINITIONS**

The term *cosmeceutical* was coined by Dr. Albert M. Kligman in the 1970s to focus on the ill-defined territory that falls between cosmetic products and therapeutic medications (drugs). Historically, topical skin care products have been divided into either cosmetics or drugs as defined by the Food, Drug and Cosmetic Act of 1938. A *cosmetic* is defined as "an article intended to be rubbed, poured, sprinkled, sprayed on, introduced into or otherwise applied to the human body or any part thereof for cleansing, beautifying, promoting attractiveness or altering appearance." The definition of a *drug* is "an article intended to affect the structure or any function of the body or articles intended for use in the diagnosis, cure, mitigation, treatment or prevention of disease in man." At a fundamental level, cosmetics alter the appearance of the skin, whereas drugs alter the structure and function of the skin.

Cosmetics do not require premarketing clearance, and it is up to the manufacturer to ensure that the ingredients and amounts used are not subject to drug regulations and that the product is safe when used as intended. On the other hand, drugs are subject to extensive premarketing research to prove their efficacy and safety. According to regulators, the intended use of a product can also determine its classification. Thus it is not only the ingredients in a skin care product but the claims in labeling and advertising that can affect its classification as a cosmetic or drug. Cosmeceuticals bridge the gap between cosmetics and drugs and refer to products that achieve cosmetic results by means of some degree of physiologic action. Other terms for cosmeceuticals are performance cosmetics, active cosmetics, functional cosmetics, and dermoceuticals.

# **COSMECEUTICAL CLASSES**

Categories of cosmeceuticals, some of which overlap, include the following:

- Retinoids
- Exfoliants
- Vitamins
- Antioxidants
- Peptides
- Growth factors

- Skin-lightening agents
- Others

#### Retinoids

The retinoids are compounds that have the basic core structure of vitamin A and its derivatives. All-trans retinoic acid is the active form of vitamin A in the skin. It works by interacting with nuclear receptor proteins to form complexes that interact with DNA sequences to affect transcription and regulation of gene expression for skin keratinocyte growth and differentiation. This causes increased cell turnover in the epidermis. All-trans retinoic acid is quite irritating to the skin and has teratogenic effects. Derivatives such as retinol are commonly used in skin care products because they are have a lower irritation profile and fewer safety concerns. Once applied to the skin, retinol converts to retinaldehyde and then all-trans retinoic acid. The science and benefits of retinoids are well documented, with proven results in reducing photodamage and fine lines of the skin as well as efficacy against acne and psoriasis.

# **Exfoliants**

The two key exfoliant cosmeceuticals are alpha hydroxy acids (AHAs) and beta hydroxy acids (BHAs). The difference in their chemical structures leads to significant differences in their mechanisms of action, although both cause superficial skin cells to desquamate at an increased rate. This results in a smoothing of skin texture and reduction in photodamage.

#### Alpha Hydroxy Acids

The most widely used AHA in skin care products is *glycolic acid* because of its excellent penetration into the epidermis due to its small molecular size. However, *lactic acid* and other larger AHAs are found increasingly in skin care products. There are many studies on the science and effectiveness of AHAs since the introduction of these products in 1974 by Van Scott and Yu. The AHAs cause desquamation of skin cells in the epidermis by reducing cellular cohesion between keratinocytes. It is postulated that AHAs bind calcium, which decreases local calcium ion concentrations from cell adhesion molecules, thus disrupting intercellular adhesion and increasing exfoliation. There are also some stimulating effects on the dermis, including increased synthesis of collagen and glycosaminoglycans, which also results in a moisturizing effect.

AHAs are very effective in the treatment of photodamaged skin as well as dry skin, seborrheic dermatitis, acne, and keratoses. Concentrations up to 10% are used in home care products, whereas higher concentrations are used in professional treatments.

### Beta Hydroxy Acids

Salicylic acid is the only BHA used extensively in skin care products. It has proven keratolytic effects and affects only the stratum corneum. It decreases cohesion between the corneocytes by denaturing glycoproteins and disrupting desmosomal attachments. It has

been used to treat hyperkeratotic conditions such as corns, warts, seborrheic dermatitis, psoriasis, and dandruff. Because salicylic acid is lipophilic, it is also very useful in the treatment of acne, and in treatment of photoaging and dyschromia. Concentrations of 0.5% to 2% are commonly used in home care products. The concentration is usually limited by the amount of irritation it causes.

#### **Amino Acid Filaggrins**

These are amino acids found naturally in skin that foster moisture retention. However, they are used topically as a mild chemical peel to reduce wrinkles and improve skin texture, although more peerreviewed research is required to define their optimal use.

### **Vitamins**

#### Vitamin C

Vitamin C is a valuable topical cosmeceutical in skin care with significant data supporting its biologic activity and benefits to the skin. Vitamin C is useful in treating photoaging because it has an antioxidant effect as well as a skin-lightening effect through tyrosinase inhibition. It is also an essential cofactor for collagen production in the skin and has proven effects on wrinkle reduction. In addition, vitamin C is helpful in treating acne because of its anti-inflammatory properties due to deactivation of some factors responsible for the production of certain proinflammatory cytokines. The active form of vitamin C is L-ascorbic acid, which is a challenge to incorporate in topical products because of stability and absorption issues. It oxidizes easily, which leads to loss of potency, and it has poor skin penetration. Enhanced delivery systems and use of more stable derivatives such as magnesium ascorbyl phosphate make the use of topical vitamin C a mainstay in skin rejuvenation treatments.

#### Vitamins B and E

Vitamin  $B_3$  (niacinamide) is used topically in skin care because it is well absorbed and well tolerated. The mechanism of action is not well elucidated, but it is a precursor to enzyme cofactors important in many cellular metabolic functions. There is some evidence that it improves the skin barrier function, which reduces skin redness and irritation. It may also reduce hyperpigmentation and improve skin texture and wrinkle depth.

Vitamin E (i.e., the tocopherols) is an anti-oxidant that is a well-documented free radical scavenger. In topical application to skin, there is good evidence that is it photoprotective, helping prevent damage from ultraviolet (UV) radiation. There is some controversy about its use in wound healing and scar prevention, and it may have some benefit in treatment of photodamaged skin.

#### Vitamin K

Vitamin K is a potent agent that increases coagulation of blood. When applied to the skin topically, there is some evidence that it may reduce bruising. There are studies showing reduced purpura after pulsed-dye laser treatments, but more research is required.

#### **Antioxidants**

Antioxidants protect the skin from free radical damage due to oxidant stress generated by sunlight and pollutants. The mechanism of action is the scavenging of singlet oxygen and reactive oxygen species. Many antioxidants have proved effective when taken orally, but not all are effective topically. The challenge is to get sufficient skin absorption of the correct form of the antioxidant agent with enough activity to achieve the desired effect. In addition to the following agents, some of the vitamins reviewed earlier are also antioxidants.

## Ubiquinone

Ubiquinone, or coenzyme Q10, has been proven to absorb after topical application to skin. There are some studies to support

improvement in photoaging of skin as well as decreased stratum corneum cell size due to a lessening of the slowdown of cell division that occurs with intrinsic aging.

# Alpha Lipoic Acid

Alpha lipoic acid is a potent antioxidant that penetrates into the dermis of skin. There is some evidence that it may reduce both intrinsic and extrinsic aging of the skin due to free radical damage, as well as decreasing UV-B—induced erythema. Further investigation and peer-reviewed studies are still required.

#### Idebenone

This newer antioxidant is a synthetic version of ubiquinone. Some initial studies indicate effectiveness in treatment of photodamaged skin, but more studies are required.

# **Peptides**

Peptides are short chains of amino acid sequences that make up larger proteins. There are three key cosmeceutical peptides that are useful topical agents for antiaging skin treatments, all with very different mechanisms of action. The cost and delivery mechanisms for these ingredients are challenging. There are limited peer-reviewed studies on these products, and research is ongoing.

# **Argireline**

Argireline (acetyl hexapeptide-3; Lipotec, Barcelona) is a hexapeptide that inhibits neurotransmitter release. It therefore can theoretically reduce muscle movement. It may decrease skin wrinkles when delivered to targeted facial muscles, such as fine lines around the eyes and lips. It does not penetrate into deep facial muscles and is not a substitute for botulinum toxin in the treatment of dynamic wrinkles.

#### Matrixvl

Matrixyl (palmitoyl pentapeptide-3), a pentapeptide fragment of dermal collagen, acts as a feedback stimulator to increase collagen synthesis. It is nonirritating to skin and preserves the barrier function of skin. It is useful in the reduction of wrinkle depth in the treatment of aging skin.

## Copper Peptide

Copper is a trace element necessary for wound healing and enzymatic processes that enhance collagen production and antioxidant activities. A tripeptide carrier may help deliver elements such as copper into the skin. The major effect of this peptide is as a delivery system rather than its own biologic activity.

#### **Growth Factors**

Growth factors are regulatory proteins that act as chemical messengers between and within cells. Hundreds of growth factors have now been identified, with many of them acting synergistically in wound healing and tissue regeneration, although their mechanisms of action are still poorly understood. Growth factors can be extracted from plants, cultured epidermal cells, placental cells, and human fibroblasts for use in cosmeceuticals. Some studies show improvement in photodamaged skin, which is similar to a chronic wound. There is also controversy about whether these molecules are too large to be absorbed, as well as theoretical concerns about their potential to contribute to hypertrophic scarring or cancerous growth. Growth factors used in skin care products include kinetin, a plant growth factor, and human growth factor (HGF).

# **Skin-Lightening Agents**

Unwanted pigmentation in the skin may be treated with a variety of cosmeceutical agents. However, only pigments in the epidermis will respond to topical agents; the deeper dermal pigments will not. Some of the aforementioned cosmeceuticals will decrease pigmentation, such as vitamins C and  $B_3$ , retinoids, and the AHAs and BHAs. Other agents also are useful as topical products to lighten pigmentation.

#### Hydroquinone

Hydroquinone (HQ) has been the standard in treatment of hyperpigmentation for many years. Its main mechanism of action is through inhibition of tyrosinase, an enzyme necessary for the production of melanin, but it may also alter the formation of melanosomes and selectively damage melanosomes and melanocytes. Although very effective, it commonly causes skin irritation and may have a cytotoxic effect on melanocytes. Concern over cytotoxicity has resulted in the banning of HQ from use in skin products in some countries.

#### **Others**

*Kojic acid* is a naturally occurring derivative from a fungus that acts as a tyrosinase inhibitor. At the 2% to 4% concentration used in skin products, it is mildly irritating and a possible allergen.

Azelaic acid, another effective skin-lightening agent, is isolated from *Pityrosporum ovale* and also inhibits tyrosinase. It is safe, although it may require a higher concentration (20%), which can cause contact dermatitis.

Other tyrosinase inhibitors, such as *arbutin* from bearberry fruit, *paper mulberry* extract from mulberry leaves, *aloesin* from aloe vera, and *glabridin* from licorice extract, may also be used as skin-lightening agents.

### **Other Cosmeceutical Agents**

#### Dehydroepiandrosterone

Dehydroepiandrosterone (DHEA) is an adrenal steroid, levels of which naturally decline with age. There is some evidence that topically applied DHEA may increase collagen synthesis and decrease collagen breakdown, although more studies are needed.

#### Dimethylaminoethanol

Dimethylaminoethanol (DMAE) is a precursor of choline that increases neurotransmitter release and muscle tone. When applied topically, it may increase muscle tone, which may cause skin tightening for skin rejuvenation. Given that other cosmeceutical peptides designed for skin rejuvenation act by doing the reverse—relaxing muscle tone to smooth out wrinkles—one can see the potential for consumer confusion and the need for more research and clinical studies.

# **SUNSCREENS**

Although sunscreens technically are not cosmeceutical agents, no discussion of skin care products is complete without reviewing sunscreens. Sunscreens are regulated by the FDA as over-the-counter (OTC) drugs and require a drug identification number (DIN). The use of a broad-spectrum sunscreen with minimum SPF 30 is important in any skin care regimen to prevent photoaging as well as skin cancers. Although in the past there has been a focus on damage caused by UV-B radiation (290 to 320 nm), we now know that UV-A radiation (320 to 400 nm) is also significant in both carcinogenesis and photodamage. UV-A has been called "the silent killer" because erythema does not occur with exposure, as it does with UV-B radiation. The SPF number listed on sunscreen labels refers to its "sun protection factor." This is the dose of UV radiation required to produce one MED (minimal erythema dose) on protected skin after application of 2 mg/cm<sup>2</sup> of product, divided by the UV radiation needed to produce one MED on unprotected skin. Because erythema is produced by UV-B radiation only, the SPF

TABLE 47-1 Common Chemical Sunscreen Agents					
UV-A Filters	UV-B Filters	UV-A + UV-B Filters			
Avobenzone (Parsol 1789) Encamsule (Mexoryl SX) Methyl anthranilate	Para-aminobenzoic acid (PABA) Cinoxate Homosalate Octyl methoxycinnamate (octinoxate; Eusolex 2292) Octyl salicylate (octisalate)	Dioxybenzone Drometrizole trisiloxane (Mexoryl XL) Octocrylene Oxybenzone (Eusolex 4360) Sulisobenzone			

rating refers to its ability to protect from UV-B and *not* UV-A. There is no standard measure of UV-A protection. It is therefore important to choose a sunscreen that provides broad-spectrum protection and lists both UV-B (an SPF rating) and UV-A radiation (no current rating available) on its label.

Sunscreens can be categorized as either physical or chemical sunscreens. Physical sunscreen agents work by physically blocking the penetration of UV radiation into the skin by reflecting or scattering light. The most common physical sunscreen agents are titanium dioxide and zinc oxide. Both of these block UV-A and UV-B radiation and are well tolerated on the skin, with a low risk of irritation. Chemical sunscreen agents work by absorbing the harmful UV rays and transforming them to harmless longer-wave radiation.

PABA (para-aminobenzoic acid) was one of the first chemical sunscreen agents available. It absorbs UV-B radiation but causes significant skin sensitivities, so it has generally been replaced by newer agents. Table 47-1 lists some of the common chemical sunscreen agents and their primary filtering actions.

Another factor to consider with sunscreens is their water resistance classification. For sunscreens to be labeled "water resistant," they must maintain their SPF level after 40 minutes of water immersion. "Very water resistant" sunscreens (formerly called "waterproof") maintain their SPF level after 80 minutes of water immersion.

### **COSMETIC SKIN CARE PRODUCTS**

In addition to the various cosmeceutical agents and sunscreens, it is important also to understand the use of cosmetic skin care products. Adults use an average of seven skin care products daily and billions of dollars are spent annually in the United States on skin cleansers and moisturizers; thus, it behooves the physician to have some understanding of skin care basics. The stratum corneum plays a key role in the use of cosmetic skin care products. The general appearance of the skin depends on the status of the stratum corneum. When it has adequate moisture, the stratum corneum is soft, pliant, and smooth and reflects light. The skin will then have a "radiance" or "glow." When the stratum corneum does not have adequate moisture, the skin will be rough and may have scaling or cracks. This roughness scatters light and the skin then has a dull appearance. Skin care involves cleansing the skin and ensuring adequate moisture content in the stratum corneum by preserving the integrity of the epidermal barrier. Skin care regimens involve the daily use of cleansers, toners, and moisturizers.

# **Cleansers**

The basic function of a cleanser is to cleanse the skin. There is a hydrolipid film covering the surface of the skin that becomes soiled through contact with dirt and pollutants as well as by secretions

from sebaceous and sweat glands. Shed corneocytes, decomposition products from the cornification process, as well as microorganisms also may contaminate this hydrolipid film. The challenge for cleansers is to remove this soil and not strip the hydrolipid film in the process, which would impair the epidermal barrier. There are two major categories of cleansers: soap/detergents and emulsion cleaning agents.

Soaps and detergents contain surfactant agents that increase the affinity of dissimilar phases for each other. This allows oil and water to mix. These are foaming cleansers and generally remove oil from skin, and thus are best as cleansers for oily skin. Soaps are the alkali salt of a fatty acid and leave an alkaline residue on the skin. This raises the pH of the skin, which increases *Propionibacteria* counts and can exacerbate acne. There are very few true soaps remaining in the marketplace; most have been replaced by synthetic detergents. Common detergent agents found in skin cleansers are sodium and ammonium lauryl sulfate, sodium laureth sulfate, cocamidopropyl betaine, and lauramphocarboxyglycinate.

*Emulsion cleaning agents* are oil-in-water emulsions or water-in-oil emulsions. They are usually cleansing milks or cleansing creams. They are less drying generally than detergents and can leave a residue of oil on the skin. These cleansers are better suited to drier skin types.

#### **Toners**

Toners are leave-on products applied to the skin after cleansing. They are designed to freshen and tone the skin and prepare the skin for the application of a moisturizer. When soaps were commonly used as cleansers, toners also served to remove the alkali residue and restore the acid mantle of the skin. In addition, toners are used to remove surface oil and debris and can be a delivery vehicle for other agents applied to the skin. Many toners have astringent agents such as witch hazel, ethanol, citrus extracts, and potassium alum as their key components. These are best for oily skin types. Alternatively, toners may have humectant agents such as propylene glycol, butylene glycol, and sorbitol, which may increase the moisture content of dry skin.

### **Moisturizers**

Moisturizers are products applied to the skin that promote and restore the epidermal barrier function and thus increase the water content of the stratum corneum. We lose approximately 500 mL of water daily through our skin (i.e., transepidermal water loss). Moisturizers are designed to maintain the water content of skin between 10% and 30%. Skin moisturizers are classified as occlusive agents, humectant agents, and emollient agents. Occlusive agents act as an enhanced skin barrier by adding a hydrophobic film to the surface of the skin. This further impairs evaporation and conserves the moisture content of the stratum corneum. Common occlusive agents include petrolatum, mineral oil, paraffin, silicone, fats, and wax. Humectant agents attract water into the stratum corneum. This water usually is drawn from the dermis, but humectants can also attract water from the environment if the ambient humidity is over 70%. It is important to note that humectants can increase transepidermal water loss if the epidermal barrier is not intact. Humectant ingredients commonly found in skin moisturizers are glycerin, hyaluronic acid, urea, propylene glycol, gelatin, honey, and sorbitol. Emollient agents are substances that fill in the cracks and crevices in the stratum corneum. They are usually also barrier agents and include substances such as mineral oil, lanolin, ceramides, silicone, fatty esters, and fatty alcohols.

Most moisturizers are formulated as *creams*, which are water-inoil emulsions, or as *lotions*, which are oil-in-water emulsions and are lighter than the cream formulations. The heaviness of the moisturizer depends on this formulation as well as the amount and characteristics of the occlusive agents. Night creams are examples of moisturizers designed as heavier creams, whereas a light, nongreasy moisturizer may be a lotion containing a weaker occlusive agent with the addition of humectant agents.

# **Choosing a Skin Care Regimen**

Proper skin cleansing and moisturizing must work in harmony to maintain epidermal barrier integrity and adequate hydration of the stratum corneum. Before choosing a skin care regimen, it is important to consider the skin condition. Note the status of the stratum corneum and the epidermal barrier and determine whether the skin is oily or dry and whether it appears dehydrated. Sensitivities should be considered. The presence of acne lesions, dyschromias, and other signs of photodamage should be noted. The environment should also be considered because humidity, temperature, wind, and pollutants are factors affecting skin care choices.

There are as many individual skin care regimens as there are products to choose from. It is impossible to give a standard skin care regimen or list all brands of skin care products on the market. The following is this author's approach and may provide some general guidance.

For oily skin types, choose a foaming cleanser with an astringent toner and lighter moisturizer with less occlusive and more humectant properties. For drier skin types, a cleansing milk or cream is preferable with a humectant toner and heavier moisturizer with increased occlusive and emollient effect.

The choice then to add cosmeceutical agents to the basic regimen depends on the desired structural changes for the skin conditions present.

For acne-prone skin, the use of lotions for moisturizing is preferable to creams. AHAs and BHAs are very beneficial in exfoliating the skin and unblocking sebaceous glands. Retinols may also be useful, as well as the anti-inflammatory action of vitamin C serums.

For hyperpigmentation, products containing hydroquinone have been the mainstay of treatment. Other lightening agents such as kojic acid and azelaic acid are beneficial, as is vitamin C serum. Exfoliating agents such as retinol should be used, and daily use of sunscreen is important.

The largest demand for skin care advice is in the realm of skin rejuvenation and the treatment of photodamage and aging of the skin. In addition to the basic skin care regimen of appropriate cleansing and moisturizing, products with active cosmeceutical ingredients are beneficial, along with a sunscreen to prevent further damage. The daily use of a medical exfoliant such as retinol and an AHA is an important step in any skin rejuvenation regimen, along with the topical application of vitamin C serum. The use of a peptide cream with Argireline and Matrixyl may also be beneficial. A broad-spectrum sunscreen with minimum SPF 30 should be used daily. Although this is one suggested approach to skin rejuvenation, there are many other cosmeceutical ingredients and regimens that may be useful.

### THE CHALLENGE OF COSMECEUTICALS

Cosmeceuticals represent the next new frontier in aesthetic medicine and the fastest-growing segment of the skin care industry. They are the driving force in the field of skin care research. However, there are very few peer-reviewed clinical trials for most of these products and there is little incentive to conduct extensive scientific research and studies. There is the concern that if research proves efficacy then the product would no longer be considered a cosmecutical, but would be classified as a drug and be subject to the rigorous governmental approval processes. The dilemma for skin care companies is that physicians require scientific proof of efficacy, yet this proof would then remove the newly developed product from the market and subject it to scrutiny as a new drug. The current confusion in the marketplace about cosmecuticals and the issue of hope versus hype versus fact is likely to remain until new regulations are in place.

# LASERS AND PULSED-LIGHT DEVICES: HAIR REMOVAL

Barry Auster • Gary Page

Photoepilation (laser hair removal) is one of a variety of methods for the removal of unwanted hair. Others include electroepilation, mechanical epilation, depilatories, and waxing. Laser hair removal has rapidly evolved over the past 10 years and there are now numerous U.S. Food and Drug Administration (FDA)—approved laser or intense pulsed-light (IPL) devices available for hair removal. The current technologies evolved from the clinical observation of hair reduction in laser-treated congenital (pigmented) hairy nevi. The potential market for laser hair removal is tremendous.

#### PRINCIPLES FOR PHOTOEPILATION WITH LASERS

Light energy emitted from a monochromatic laser (a single wavelength of light) or an IPL source (produces a broad spectrum of light using filters to block unwanted wavelengths) is absorbed by a pigmented object (in this case, hair) and is converted into heat energy. This heat energy destroys the hair follicle, causing a long-term reduction in hair growth. This process of transforming light to heat energy and destroying targeted pigmented tissue is called *selective photothermolysis*.

The concept of selective photothermolysis was first presented by Anderson and Parrish in 1983. This is the process by which thermal damage is confined to the particular target tissue. It is based on two important concepts. The first is that chromophores (e.g., hair, blood vessels, melanosomes/pigment) are objects that preferentially absorb light of specific wavelengths (Fig. 48-1). The second is thermal relaxation time (TRT), which is defined as the time required for an object to cool to 50% of the temperature resulting from laser exposure. When the target tissue absorbs the laser light, energy is changed to heat, which causes thermal tissue damage and heat transference to the surrounding tissues. For lasers, pulse width is the duration (in milliseconds [msec]) that the light energy is applied. A laser with a pulse width less than the TRT of the target conducts very little heat to the surrounding tissues. Consequently, it is possible to confine the laser's destructive effect to a specific area of tissue based on the chromophore content and the rapidity at which the light energy is applied (Fig. 48-2).

Lasers are monochromatic, which means the light is of a single wavelength or color. Each type of laser has a different wavelength and each chromophore absorbs the specific light energy in that laser wavelength, converting it to thermal energy. Melanin is the target chromophore for photoepilation. Hemoglobin, another chromophore, is targeted to destroy vascular lesions. Water and collagen are also chromophores. Each chromophore has a spectral absorption pattern that determines the wavelengths of light that are most absorbed and converted to thermal energy. It is important to match the wavelength of the laser with the specific chromophore for targeted destruction and to avoid damage to adjacent tissues. The amount of energy needed to destroy the hair follicle is usually close to the

energy level at which skin damage occurs. Determining the treatment energy level for a particular patient without causing excessive surrounding tissue damage is the most clinically demanding task. Certain types of lasers are then chosen because they are more effective at destroying hair follicles without causing excessive surrounding damage, which could lead to burns or scarring.

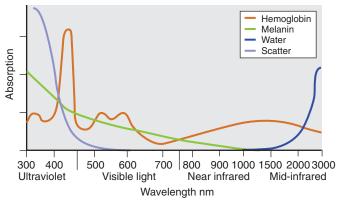

The lasers used for epilation fall into four categories: alexandrite (755 nm), neodymium-doped yttrium aluminum garnet (Nd:YAG; 1064 nm), ruby (694 nm), and diode (810 nm).

Treatment tip or spot sizes vary from 2 to 15 mm, and pulse widths vary from 10 to 100 msec. In addition, the repetition rate can vary from 1 to 10 or more pulses per second (hertz). Faster repetition rates improve efficiency in treating larger areas such as the back or legs. The size of the area being affected by each burst of energy (spot size) is variable from machine to machine and from laser tip to laser tip. In general, the larger the spot size, the greater the depth of light penetration at the same energy level. Lasers and IPL machines most often measure the energy level delivered to the skin in joules per square centimeter (J/cm²), also known as *fluence* (Fig. 48-3A).

Intense pulsed-light (Fig. 48-3B and C) devices are flashlamp devices that emit light over the entire visual spectrum and hence are not monochromatic like lasers. Specificity for different hair colors and skin types may be achieved with various cut-off filters and fluence settings. Recently, IPL devices have increased in popularity because of their versatility and cost effectiveness. With one device and multiple handpieces/filters, physicians can treat most conditions. With regard to photoepilation, IPL devices are now equally as efficacious as lasers. In addition, a hybrid device (Syneron) uses a combination of IPL followed by radiofrequency. It is based on the principle of electrical impedance, whereby electrical energy flows preferentially to a warmer target. This device reportedly has some beneficial effects for gray and white hairs.

The ideal patient for photoepilation is someone with light skin and dark hair, so that all the generated thermal energy is focused on the melanin chromophore of the hair. Light hair is very difficult to treat because it is not differentiated from the surrounding light skin. Studies are ongoing using a melanin dye (Melamax; Creative Technologies, Chesapeake, VA) that is driven into the hair root by an ultrasound device. Preliminary data showed modest improvement in the effect of hair removal lasers on white or blonde hair. The effect was greater on vellus than terminal hairs. Similarly, it is very difficult in most instances to treat black hair on black skin. When patients are tanned, care must be taken lest the skin itself be burned during the treatments.

Cooling during treatment is important. IPL devices contact the skin and use a combination of a chilled gel and a chilled sapphire tip. The latter is a vast improvement over glass tips, which cracked frequently from the stress of temperature changes. Some devices

**Figure 48-1** Relative absorption of light by biologic tissues. By selecting specific wavelengths of light, a selective effect on biologic tissue is achieved. Whenever light hits tissue, it can be transmitted, scattered, reflected, or absorbed, depending on the type of tissue and the selected wavelength(s) (color) of the light. However, light *absorption* and subsequent tissue heating must take place to achieve any biologic effect, and a given wavelength of light may be strongly absorbed by one type of tissue and be transmitted or scattered by another. Different tissues have different absorption characteristics depending on their specific components (i.e., skin is composed of cells, hair follicles, pigment, blood vessels, sweat glands). The main absorbing targets, or chromophores, of tissues are (1) hemoglobin in blood; (2) melanin in skin, hair, and moles; and (3) water (present in all biologic tissue).

(e.g., LightSheer Diode Laser; Lumenis, Santa Clara, Calif) use a cold-water chamber to cool tissue. Dynamic cooling devices use a chlorofluorocarbon, U.S. Environmental Protection Agency–approved refrigerant spray. This is available only on lasers produced by Candela (Wayland, Mass), which has proprietary rights to the technology. A final alternative chilling method is using cold air blown on the site being treated (Zimmer MedizinSystems Corp., Irvine, Calif).

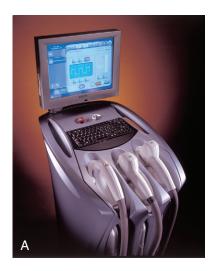

The FDA has recently approved a home-use laser (TRIA Beauty, Dublin, Calif) for hair removal. This is a diode laser and costs approximately \$600. Preliminary data, although limited, show beneficial results.

# HAIR GROWTH PHASES AND TREATMENT IMPLICATIONS

Hair follicles have been difficult to treat with lasers. There is a wide variation in depth at different anatomic sites, with the deepest follicular bulbs at 5 mm. This is beyond the range of penetration of

**Figure 48-2** Three principles of selective photothermolysis: (1) Penetrating wavelength of light should be absorbed selectively by target tissue; (2) pulse duration should match thermal relaxation time of target tissue; and (3) sufficient fluence (J/cm²) should be applied to damage target tissue. (Redrawn from a presentation by Brian Zelicksen, MD, American Society for Laser Medicine and Surgery Meeting, April 2002.)

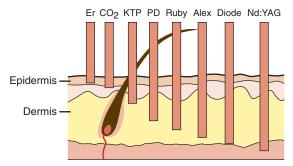

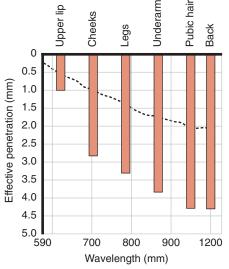

**Figure 48-3** Intense pulsed-light and laser system. **A,** Lumenis One. **B,** LightSheer handpiece. **C,** Multi-Spot Nd:YAG handpiece. (Courtesy of Lumenis, Santa Clara, Calif.)

#### Depth as a result of wavelength

**Figure 48-4** Depth of penetration of various cutaneous lasers. Alex, alexandrite; Er, erbium; KTP, potassium titanyl phosphate; PD, pulsed dye.

**Figure 48-5** Depth of hair follicles in different body locations. *Dotted line* indicates penetration depth of light frequency.

Figure 48-6 The different phases of the hair cycle: anagen, catagen, and telogen. Labeled structures include arrector pili muscle (APM), bulge (B), cortex (C), dermal papilla (DP), epidermis (E), inner root sheath (IRS), matrix (M), medulla (Md), outer root sheath (ORS), and sebaceous gland (S). B and B\* denote quiescent and activated bulge cells, respectively. Follicular structures above the dotted line form the permanent portion of the follicle; keratinocytes below the bulge degenerate during catagen and telogen. (Redrawn from Cotsarelis G, Sun TT, Lavker RM: Label-retaining cells reside in the bulge area of pilosebaceous unit: Implications for follicular stem cells, hair cycle, and skin carcinogenesis. Cell 61:1329–1337, 1990.)

most lasers (Figs. 48-4 and 48-5). Whereas upper lip hair follicles range from 1 to 2.5 mm in depth, pubic and axillary hairs may lay as deep as 5 mm. In addition, most authorities agree that *only the anagen phase* of follicular growth is responsive to laser-induced thermal energy damage. The percentage of follicles in the anagen phase at any one anatomic site varies from 30% on the trunk to as high as 80% on the scalp. Therefore, to understand laser hair removal more fully, a knowledge of hair anatomy and development is necessary.

Hair is composed of keratinous fibers that grow from follicles over the entire body surface except the palms and soles. The number of follicles is finite at birth. Growth involves three stages (Fig. 48-6). Anagen is the active growth phase of the hair follicle, during which the hair contains abundant melanin. Catagen is a period of regression when cell division terminates in the long part of the follicle and the lower part of the follicle begins to involute. The final, resting phase is called telogen, during which the old hair is emitted and shed before the development of a new hair begins. During telogen there is very little or no melanin in the follicle and hence laser treatments will have very little to no effect. The length of these three individual phases of hair growth varies widely with anatomic site (Table 48-1). Because of this, patients must be advised that 100% hair reduction may be impossible because of the relative unresponsiveness of the telogen follicle to laser photoepilation. Hairs, particularly on the trunk, may remain in telogen for longer than 3 months. Therefore, patients need to be advised that followup treatments may be needed up to 1 year after initiation of therapy to allow for conversion of telogen hairs to anagen.

Hairs are of two types: *terminal hairs* are thick, long, and pigmented with melanin and found throughout the body surface, whereas *vellus hairs* are thin, short, and depigmented.

Figure 48-6 demonstrates the structure and life cycle of a typical hair. The hair itself grows from the bulb, which consists of the hair matrix and the dermal papilla. The *papilla* is an area of highly vascularized connective tissue that provides the nutrients for the rapidly dividing cells of the matrix. During periods of active growth, matrix cells divide every 24 to 72 hours and migrate upward to become keratinized and packed into layers that compose the *hair shaft*.

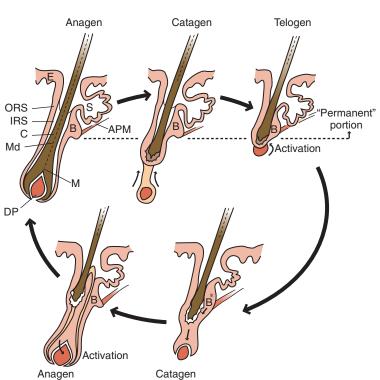

TABLE 48-1	Hair Depth and Hair	· Cycle			
Body Area	Telogen Hair (%)	Anagen Hair (%)	Telogen Duration	Follicles Density (I/cm²)	Follicle Depth (mm)
Scalp	13	85	3–4 mo	350	3–5
Beard	30	70	10 wk	500	2–4
Upper lip	35	65	6 wk	500	1–2.5
Axillae	70	30	3 mo	65	3.5-4.5
Trunk	70	30	12 wk	70	2–4.5
Pubic area	70	30	12 wk	70	3.5-4.5
Arms	80	20	18 wk	80	2.5-4
Legs and thighs	80	20	24 wk	60	2.5-4
Breasts	70	30	12 wk	65	3–4.5

The "bulge," which is a protrusion near the attachment of the arrector pili muscle, has recently been determined to consist of stem cells important in hair regeneration. The bulge is generally located 1 to 1.5 mm below the cutaneous surface. As mentioned previously, hairs grow in recurrent cycles (see Table 48-1). Therefore, the target of laser thermolysis is twofold: the bulge and the papilla.

# FITZPATRICK SKIN TYPES AND TREATMENT IMPLICATIONS

As the thermolytic hair removal technique has developed, it has become clear that proper patient selection is critical for success. The two preeminent factors in patient selection are skin type and hair color (Fig. 48-7). Skin types are based on the Fitzpatrick classification system:

Type I Always burns, never tans
Type II Always burns, sometimes tans
Type III Sometimes burns, always tans
Type IV Rarely burns, always tans
Type V Moderately pigmented

Type VI Black skin

Fitzpatrick grouped patients into the six different skin types based on the amount of pigmentation found in the skin. Skin type I has the least pigment and type VI has the most. The lower skin types are most sensitive to ultraviolet (UV) radiation ("sunburn") and to development of solar damage such as pigmentation, skin thinning, actinic changes, and skin cancer. More freckles are also found in skin types I and II and fewer in type III and above. The higher the skin type, the more melanin is present in the epidermis and the more resistant the skin is to sunburn. Hair removal treatment is easier in patients who are most sensitive to UV radiation because they have less melanin *in their skin* to absorb the therapeutic light. More light energy passes through to the hair follicles itself and there is less risk of photothermal damage to the skin.

In general, skin types I and II are most easily treated. Types III, IV, and V are more difficult to treat. Skin type VI may be treated only in rare circumstances. Because of increased epidermal melanin, there is a higher risk of thermal damage to the skin in types V and VI, which may cause scarring or pigmentary alterations such as hypopigmentation or postinflammatory hyperpigmentation. Only a few devices (Nd:YAG and diode lasers) have received FDA approval to treat type VI skin. Extreme care must be taken in treating type V and VI skin types, particularly if the hairs are fine or light. Permanent dyspigmentation may occur if such patients are overtreated.

# **INDICATIONS**

- Hypertrichosis
- Hirsutism

- Cosmetic (e.g., bikini lines)
- Pseudofolliculitis barbae

Hypertrichosis, excessive vellus or lanugo hair, may be localized or generalized and may occur in both men and women. It is not related to excess testosterone.

Hirsutism involves development of coarse terminal hair (e.g., on the face) in children or women resulting from increased levels of male hormone. In women, the most common clinical causes are congenital adrenal hyperplasia and polycystic ovaries. If a woman demonstrates symptomatology of these disorders (e.g., irregular menses, infertility, obesity, acne), then appropriate laboratory testing should be performed. These tests should be carried out under fasting conditions and include insulin level, glucose, luteinizing hormone, follicle-stimulating hormone, prolactin, dehydroepiandrosterone (DHEA), and free testosterone. If a woman does demonstrate androgen excess, referral to an endocrinologist is appropriate. Spironolactone, a competitive inhibitor of DHEA binding, may be used supplementally and also is effective in women with hypertrichosis without androgen excess.

Pseudofolliculitis barbae resulting from ingrown hairs is improved dramatically by photoepilation. By reducing the number of hairs, the severe infection may be significantly diminished and the patient's symptoms markedly improved. Although there may be some pigment changes, they may improve over time and the risks may be outweighed by the benefit to the patient's quality of life. Unwanted permanent hair loss may also occur because of treatment.

# **CONTRAINDICATIONS**

## **Absolute**

- History of keloids
- Isotretinoin (Accutane) use in past 6 months

#### Relative

- Herpes simplex (active; use antiviral drugs if there is a history starting the day before and continuing for 5 days afterward)
- Photosensitizing medications (e.g., St. John's wort, tetracycline, thiazides, captopril)
- Recent plucking, waxing, or electrolysis
- Pregnancy (a general precaution; no adverse effects are known)
- White hair
- Recently tanned skin (relative, because degree of tan is important, and only a change in the parameters for treatment may be required; patients with a tan should know that treatments must be more conservative and therefore may not show the optimal benefit)

Individuals with a history of herpes simplex should be treated prophylactically with antiviral drugs before and during treatment. Individuals who have been on isotretinoin within 6 months tend to have adverse healing and susceptibility to hypertrophic scarring. In addition, patients on photosensitizing medications or supplements may be treated, but treatment settings should be conservative. Because the hair itself is the major chromophore for the laser, patients should be advised to *avoid* waxing, electrolysis, plucking, depilatories, or shaving immediately before treatment because the resulting inflammatory process generally involves more pigmented changes, which will absorb the light energy. In female patients who have plucked hair on a daily basis, the latter requirement may present a difficult conundrum because an effective treatment requires approximately 1 mm of hair protruding above the skin surface. Between treatments, patients are allowed to continue their own hair removal methods, with shaving being the preferred method.

#### **SAFETY ISSUES**

Physicians who use lasers for hair removal should be acutely aware of the potential for ocular damage. All of the devices may cause blindness. The importance of eye protection for both the practitioner (or technician) and the patient is paramount and cannot be overstressed. Laser goggles should be labeled with the wavelength they block. When working around the orbit, metallic, totally occlusive goggles are preferred (Oculo-Plastik, Inc., Montreal, Quebec); in some cases a corneal shield inserted under the lids is best. The laser or IPL handpiece must be carefully guarded, and those using it must ensure that it is pointed away from the eyes at all times. Some office practices designate one of the clinical personnel as the "laser safety officer" in charge of ensuring that eye protection is worn by all in the treatment rooms and that warning signs are posted outside the door when the laser is in operation. The warning sign should be taken down when the laser is not in use or the sign will soon be ignored.

# FACTORS INFLUENCING TYPE OF EQUIPMENT USED

- Reliability
- Purchase price
- Technical support
- Training provided
- · Cost of maintenance contract
- Space needed in office for storage
- Disposable materials cost
- Ease of operation
- Warranty period
- Length of time the particular company representative has been "in the business"

Purchasing a hair removal device is a challenging task. It is important to determine the reliability of the unit, the available warranty, and exchange and support contracts, including costs, because these units are mechanically complicated and do break down. The cost of a service contract should be considered part of the acquisition cost. Even more important is the educational support and training provided by the company for current and future staff members. All units have a learning curve, and training seminars with on-site education on an ongoing basis are crucial for safety and efficacy of treatments. Appropriate technical support is also an important consideration, as are anticipated upgrades. Repairs must be guaranteed on a timely basis. Finally, it is prudent to have frank discussions with physicians who currently use and have experience with the equipment being considered.

# **EQUIPMENT**

- 4 × 4 gauze pads.
- Hair clippers.
- Alcohol to cleanse the skin.
- Cooling gel or Zimmer Chiller (depends on device used).

- Topical anesthetic. EMLA (eutectic mixture of local anesthetics) cream is preferable because of its vasoconstrictive effect, which reduces the competing chromophore of hemoglobin. Many offices use topical anesthetics prepared by specialty pharmacies that contain much higher concentrations of lidocaine. Recently, the FDA has begun to look into these formulations because they have not been tested for safety. Operators should be aware that these agents may be absorbed percutaneously with resultant neurologic and cardiac effects. There have been several deaths reported from overuse of these agents topically. Care should be taken to apply limited quantities and to avoid occluding them if large areas are involved. (See Chapter 5, Local and Topical Anesthesia Complications, and Chapter 10, Topical Anesthesia.)
- Protective laser eyewear (goggles and metal eyepieces).
- Laser/IPL equipment.
- Cooling pack/ice for post-treatment care.
- Smoke evacuator or a room exhaust fan to remove the smell of burning hair.
- For offices that have not previously used lasers there are certain U.S. Occupational Safety and Health Administration (OSHA) requirements for the treatment room. There should be no mirrors, or any present must be covered with paper. If the room is on the first floor it should have no windows or they should be covered with blackout shades. If the door to the room has a window it should also be covered. The door also should have a sign on the outside that says "Laser in Use." Although uncommon, OSHA inspections may result in fines in the tens of thousands of dollars if infractions are discovered.

#### PREPROCEDURE PATIENT PREPARATION

The patient should fill out the aesthetics questionnaire form (see Chapter 46, Introduction to Aesthetic Medicine, Fig. 46-1) and be supplied with educational materials before the visit with the clinician (see patient education and consent forms online at www. expertconsult.com). The patient must not tan for 4 weeks prior and should not pluck any hair for at least 5 days prior.

It is extremely important to know the medical history, including use of medications and tanning history, and to determine Fitzpatrick skin type. The power settings for the full treatment are determined at this time and recorded. During the initial visit, many practices perform test patches with the settings that will be used. This is particularly important in types V and VI skin. For the darker skin types, adverse reactions such as edema and crusting may become evident up to 2 days after treatment. Some practitioners will treat the ideal patient (Fitzpatrick type I or II with dark brown or black hair) at this initial appointment, but will observe the effect of the test spots on other skin types before initiating the full treatment.

A useful adjunct for patients who have a combination of coarse and fine hairs is topical effornithine (Vaniqa; SkinMedica, Inc., Carlsbad, Calif). This product inhibits hair growth. It is useful for vellus hairs and does not affect the treatment of terminal hairs. It can be used to improve the overall appearance at completion of the treatment process and can be started immediately after the consultation session. However, hair growth tends to recur once the medication is stopped.

# PROCEDURE AND TECHNIQUE OF HAIR REMOVAL

- 1. The patient's skin type is determined on the Fitzpatrick skin type scale (see Fig. 48-7).
- 2. Proper settings are selected (individualized with each unit). Each company will provide training with its particular unit. The settings are too variable to list individually here.
- 3. The hair is clipped to a 1-mm length.
- 4. The skin is wiped with alcohol.
- 5. Various topical anesthetics may be used before treatment.

## **Skin Typing**

For successful hair removal, it is necessary to determine the correct typing of your skin. Your doctor will consider your skin type when planning your treatment program.

Skin type is categorized by the Fitzpatrick skin type scale, which ranges from Type I (fair) to Type VI (black). The main factors that influence skin type are genetic disposition and reaction to sun exposure and tanning habits.

Skin type is determined genetically and is one of the many aspects of overall appearance. Genetics also determines the eye color, hair color, and the way skin pigments react to light. The way your skin reacts to sun exposure is important in correctly assessing your skin type. Sunbathing or artificial tanning (e.g., tanning creams) affects the evaluation of your skin color.

Please take a few minutes and fill out this questionnaire to help us determine your skin type and treat you properly.

### **Genetic Disposition**

	0	1	2	3	4	Score
What color are your eyes?	Light blue, gray, green	Blue, gray, green	Blue	Dark brown	Brownish black	
What is the natural color of your hair?	Sandy red	Blonde	Chestnut/dark blonde	Dark brown	Black	
What color is your skin (unexposed areas)?	Reddish	Very pale	Pale with beige tint	Light brown	Dark brown	
Do you have freckles on unexposed areas?	Many	Several	Few	Incidental	None	
	Genetic Disposition Total					

#### **Reaction to Sun Exposure**

	0	1	2	3	4	Score
What happens when you stay too long in the sun?	Painful redness, blistering, peeling	Blistering followed by peeling	Burns sometimes followed by peeling	Rare burns	Never had burns	
To what degree do you turn brown?	Hardly or not at all	Light tan	Reasonable tan	Tan very easy	Turn dark brown quickly	
Do you turn brown with several hours of sun exposure?	Never	Seldom	Sometimes	Often	Always	
How does your face react to the sun?	Very sensitive	Sensitive	Normal	Very resistant	Never had a problem	
	Reaction to Sun Exposure Total					

Figure 48-7 Sample form to determine skin type. (Courtesy of John L. Pfenninger, MD, The Medical Procedures Center, PC, Midland, Mich.)

- The cooling gel is applied; most lasers and IPL devices have integrated cooling systems.
- 7. Eye protection is provided to the practitioner and the patient.
- 8. Photoepilation is performed.
- 9. Observe for the proper tissue reaction (see later discussion).
- 10. Ice packs or chilled aloe gel are applied.
- 11. Follow-up sessions are scheduled.

At the treatment session, hairs are clipped to a 1-mm length because if long hairs are left on the skin surface there is a risk that they will act as a heat sink and singe the underlying epidermis. Protective goggles are placed on the patient, laser operator, and

anyone else present in the room. Proximity of the spot treatments varies from one device to another, but in general they should either be abutted or slightly overlapped (10% to 20%). Observation of clinical response during the treatment is essential. If either obvious burning of the skin or no effect to hairs or follicles is noted, energy fluences should be adjusted accordingly. The ideal cutaneous response is discrete perifollicular erythema and edema without coalescence into solid erythema. Observe for shearing or fracture of about 20% to 30% of the hairs during the treatment session and note the "sulfur" smell of thermally damaged hair. Patients should be advised that additional hairs will fall out over the ensuing 2 to 3 weeks (Figs. 48-8 through 48-10).

	1	2	3	4	5	Score
When did you last expose your body to sun (or artificial sunlamp/tanning cream)?	More than 3 months ago	2–3 months ago	1–2 months ago	Less than a month ago	Less than 2 weeks ago	
Did you expose the area to be treated to the sun?	Never	Hardly ever	Sometimes	Often	Always	

Add up the total scores for each of the three sections for your Skin Type Score. This will give you a better evaluation of your skin type.

# **Summary**

Genetic Disposition Total	
Reaction to Sun Exposure Total	
Tanning Habits Total	
Skin Type Score	

# Your Fitzpatrick Skin Type

Skin Type Score	Fitzpatrick Skin Type
0–7	I
8–16	II
17–24	III
25–30	IV
Over 30	V–VI

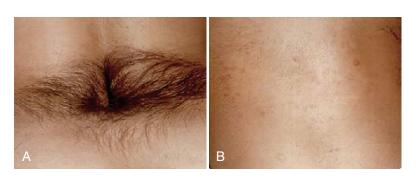

**Note:** This questionnaire is intended as a guideline for skin typing. Final evaluation of skin type should be determined by your doctor.

### **COMPLICATIONS**

- Anesthesia complications: Topical anesthetic creams may be used before treatment, but caution should be used because some deaths have been attributed to toxicity of anesthetics applied under occlusion over large areas.
- Discomfort associated with photoepilation is generally mild and transient and has been described as similar to a large rubber band snapping against the skin when the light pulse is triggered. If the patient reports severe pain during the treatment, this should be considered as an indication of excessive energy with the potential for significant thermal injury. Power should be immediately lowered and ice applied if the treated sites appear bright red or edematous.
- Ocular burns and blindness.
- Second-degree burns.
- Hypopigmentation is a difficult problem to treat but it usually improves on its own over a period of months to years.
- Postinflammatory hyperpigmentation may be treated with prescription as well as over-the-counter bleaching creams, light chemical peeling, or even pigment-specific lasers. Over-the-counter bleaching agents contain 2% hydroquinone and are modestly effective for this problem. Prescription agents containing 4% hydroquinone combined with tretinoin and fluocinolone (e.g., Tri-Luma Cream; Galderma Laboratories, Ft. Worth, Tex) are far more effective.
- Scarring: Hypertrophic scarring or keloids should be treated with currently acceptable modalities, which include intralesional steroid injections, silicone gel sheathing, and pulsed-dye laser treatments.
- Lack of satisfactory response with regrowth.
- Stimulation of hair growth (rare): This is a rare event but does occur
  more commonly in dark, type III or IV skin types. This may be
  due to a biostimulatory rather than destructive effect. If it occurs,
  treatment with an alternative, longer-wavelength laser should be
  attempted.

### POSTPROCEDURE PATIENT EDUCATION

The patient should be given the following instructions and advice:

- Do not pick at any skin peeling that may occur.
- Plucking residual hair is acceptable after treatment.
- Soothing gel, lotion, or cool packs may provide comfort.
- Makeup can be applied after 2 hours.
- Erythema may last for several hours.
- Sunscreen (SPF  $\geq$  30) should be used between sessions.
- Multiple treatments will be required at all anatomic sites, but the number varies.
- Treatment intervals will be every 3 to 4 weeks or longer depending on the site for five to six treatment sessions, then every 3 months for a year.

Cool compresses can be applied for 2 to 3 hours after treatment but are usually not needed after this time. On occasion, patients

experience blistering that causes crusting. This usually does not occur until the following day. If it does occur, the patient can apply warm compresses and a topical antibiotic ointment. Future treatments will require that the settings be adjusted.

# **CONCLUSION**

Photoepilation is a well-developed technology in the cosmetic medical field. Compared with electrolysis, treatments are more rapid, more comfortable, and more effective. The key to a successful laser hair removal practice is correct selection of patients for whom the treatment would be effective. Patients with dark skin types and light hair are poor candidates. Providing appropriate expectations for the patients before the onset of treatment is crucial. As our understanding and experience with this technology improve in the future, improved treatment responses as well as more acceptable home-use devices are likely to be seen.

# **CPT/BILLING CODE**

17380 Electrolysis, epilation, each half-hour

#### **ICD-9-CM DIAGNOSTIC CODES**

704.1 Hirsutism, hypertrichosis

704.8 Pseudofolliculitis barbae

704.9 Disease of hair and follicle, NOS

#### **CHARGES**

A wide variation in charges for photoepilation exists between practices and within a practice. Variables that determine pricing include local competition, cost of equipment, size of the area being treated, and the duration of the treatment. Larger treatment areas require more provider or technician time and cause more "wear and tear" on the equipment. The majority of hair removal is considered to be cosmetic and thus patients need to pay out-of-pocket at the time of service. It is important that they understand this and sign an agreement beforehand stating the fees are known to them.

# LASERS AND PULSED-LIGHT DEVICES: PHOTOFACIAL REJUVENATION\*

Renier van Aardt

In 1983, Anderson and Parrish described the concept of selective *photothermolysis*. Their article simply stated that the matching of a specific wavelength and pulse duration of light can obtain selected effects on a targeted tissue with minimal changes to surrounding structures.

This was a breakthrough in the application of light and laser technology for the purpose of skin rejuvenation. Dr. Patrick Bitter is credited for developing the treatment and for coining the word *photofacial*, referring to the cosmetic improvement of facial skin using nonablative light-based technology.

Lasers have a relatively short history in medical use. In 1964, the Nd:YAG (neodymium-doped yttrium-aluminum garnet) laser and  $\mathrm{CO}_2$  (carbon dioxide) laser were developed at Bell Laboratories. Researchers found that a  $\mathrm{CO}_2$  laser beam could cut tissue like a scalpel, but with minimal blood loss. The surgical uses of this laser were investigated extensively from 1967 to 1970 by pioneers such as Thomas Polanyi and Geza Jako, and by the early 1970s use of the  $\mathrm{CO}_2$  laser in ear/nose/throat and gynecologic surgery had become well established but was limited to academic and teaching hospitals.

The single most significant advance in the use of medical lasers was the concept of "pulsing" the laser beam, which allowed for the aforementioned selective photothermolysis. The first lasers to fully exploit this principle were the pulsed-dye lasers introduced in the late 1980s for the treatment of port wine stains and strawberry birthmarks in children and, soon afterward, the first Q-switched lasers for the treatment of tattoos.

Another major advance was the introduction of scanning devices in the early 1990s, enabling precision computerized control of laser beams. Scanned, pulsed lasers revolutionized the practice of plastic and cosmetic dermatologic surgery by making safe, consistent laser resurfacing possible.

In recent years, the main focus of dermatologic laser research and development has been on laser hair removal, photorejuvenation, and the treatment of vascular lesions, including leg veins, using lasers and intense pulsed light (IPL). The thrust of current research is directed toward nonablative laser resurfacing (e.g., laser skin toning, photofacial), fractionated ablative resurfacing, plasma resurfacing, and improved photodynamic therapy (for treatment of sun damage and skin cancer and for hair removal).

The treatment known as *photofacial rejuvenation* stems from the inherent human desire to be socially acceptable and to appear young and attractive. Social pressure demands a flawless skin; when obvious blemishes are present, the individual can suffer significant psychological trauma. Patients seek treatments that will improve facial blemishes such as pigmented lesions, vascular lesions, scars, texture, rhytids, and tone without downtime and preferably without risk.

Skin deterioration is the result of a number of external and internal factors. The most common external factor is ultraviolet (UV) light from prolonged sun exposure as well as the popular use of tanning beds. The effects of UV light are cumulative over a person's lifetime and can result in telangiectases, matting, poikiloderma, broken capillaries, actinic keratoses, skin cancer, seborrheic keratoses, solar lentigines, progression of chloasma and melasma, textural deterioration, accelerated skin atrophy, redundant skin, and the formation of rhytids. These findings are more likely in patients with lighter skin types (Fitzpatrick types I, II, and III) who have less natural defense against UV light, resulting in more severe sun damage. Patients with sun-damaged skin are usually good candidates for IPL photorejuvenation, although expectations should be realistic and focused on the improvement of chromophores (pigmented spots) rather than rhytids. Mild to moderate rhytids can be improved with fractional, plasma, and ablative technologies, as outlined in the next section.

Internal factors that cause the skin to lose its youthful appearance include acne, rosacea, chronic illness, endocrine diseases, skin diseases, drug abuse, smoking, and congenital skin lesions.

It is therefore essential for any person desiring attractive skin in later life to practice healthy lifestyle habits, including sun avoidance and regular use of topical sun protection products, not smoking, and consuming a healthy diet and ample water. The degree of improvement of lesions will vary depending on the origin and characteristics of the lesion and the chosen treatment modality and parameters.

#### **INDICATIONS**

# Type I Photorejuvenation (Intense Pulsed Light and Fractional Laser)

- Mild to moderately photoaged skin
- Benign vascular lesions (telangiectases, flushing, symptoms of rosacea)
- Dyschromia
- Erythema after laser resurfacing
- Pigmentary sun damage
- Mottled pigmentation
- Hyperpigmentation
- Lentigines

# Type II Photorejuvenation (Fractional and Ablative Lasers)

- Dermal and epidermal structural changes
- Rhytids
- Elastotic changes
- Collagenous and connective tissue changes
- Large pores

<sup>\*</sup>Photofacial is defined as facial skin treatment using light-based technology.

**Figure 49-1** Appearance of the skin after application of the fractional laser, showing the typical areas of ablation (dots) and the spared areas in between that allow a much more rapid healing time. The treatment causes macroscopic erythema and edema that typically resolve within 24 hours. The beneficial effects of collagen contraction and skin tightening may continue for 4 to 6 months.

#### TREATMENT TYPES

Photofacial treatment can be categorized into two main types: ablative and nonablative. Ablative treatment vaporizes tissue at very high temperatures, whereas nonablative treatment uses gentler heat that may denature protein in certain targets but is insufficient to vaporize tissue. Photofacial treatments can be subdivided further into those that produce downtime versus those that have little or no downtime. Nonablative technologies typically do not produce significant downtime, whereas ablative treatment at a reasonable depth of treatment does. The exception is fractional ablative therapy, where tiny islands of tissue known as microscopic treatment zones (MTZs) are destroyed. The areas of normal tissue between the treated areas allow for a much more rapid healing time and little, if any, downtime (Fig. 49-1). The treatment causes macroscopic erythema and edema that typically resolves within 24 to 72 hours. The success of both ablative and nonablative laser treatments still depends on the skill of the operator. Figure 49-2 shows the pattern and depth of various treatments.

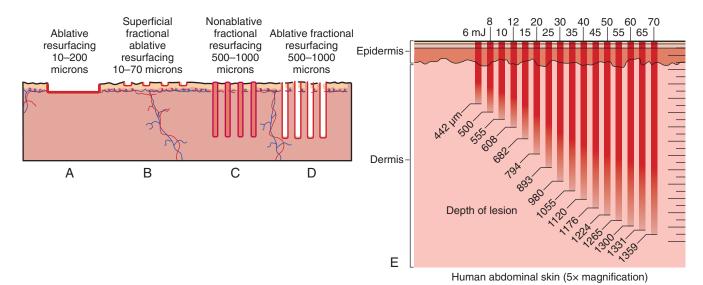

#### **Ablative Laser**

The two most commonly used ablative lasers are the CO<sub>2</sub> laser and the erbium laser. The CO<sub>2</sub> laser was the first to be used for ablative skin resurfacing and tends to create coagulation and significant bulk heating of the skin, and therefore carries a higher risk of complications such as hypopigmentation and permanent scarring. In skilled hands it remains the most effective way to achieve the best results in skin rejuvenation. CO<sub>2</sub> lasers emit light in the near-infrared region at 10,600 nm. They target intracellular water, which heats cells instantly to more than 100° C, resulting in vaporization and removal of a surface layer of cells, coagulation necrosis of cells and denaturing of extracellular proteins in a subjacent residual layer, and nonfatal damage to cells in a still deeper zone. The entire epidermis and a variable thickness of dermis are removed, with a resultant smoother skin due to heat-induced shrinkage of deeper collagen. Patients must accept post-treatment edema, burning, and crusting and an average of 4.5 months of post-treatment erythema. Traditional ablative therapy carries the risk of pigmentary changes, acne flares, herpes simplex virus infection, scars, milia formation, and dermatitis.

Erbium (Er:YAG) lasers are solid-state lasers whose lasing medium is erbium-doped yttrium aluminum garnet (Er:Y<sub>3</sub>Al<sub>5</sub>O<sub>12</sub>). The erbium laser has become a more popular resurfacing modality than the  $\rm CO_2$  laser because of its precision and lower degree of bulk heating. It also targets intracellular water at 2940 nm, but it is considerably less ablative than the  $\rm CO_2$  laser. The ablation is more superficial and wounds heal more quickly, but it is less effective at equal fluence and with a similar number of passes compared with the  $\rm CO_2$  laser. To achieve an effective thermal damage effect to improve solar elastosis and rhytids, a longer pulse duration is required when using the erbium laser. A combination of erbium and  $\rm CO_2$  lasers may be used as an alternative to the  $\rm CO_2$  laser alone.

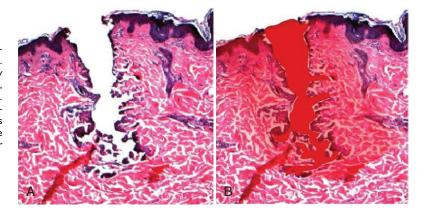

# **Nonablative Laser**

Nonablative lasers can be used to selectively injure the dermis or a target in the skin while protecting the epidermis by cooling during treatment, such as the Nd:YAG laser used for collagen remodeling

**Figure 49-2** Diagram illustrating the difference between ablative and fractional resurfacing. **A,** Superficial layer of tissue is completely vaporized. **B,** Columns of tissue have been vaporized, leaving areas of normal tissue in between, which speeds healing. **C,** Nonablative fractional resurfacing, showing heated (injured) tissue that remains in the microchannels. **D,** Ablative fractional treatment with the tissue in the microchannels vaporized. Ablative and nonablative fractional laser treatments can essentially penetrate to the same depth; however, ablative laser vaporizes tissue, whereas nonablative laser leaves a plug of necrotic debris. **E,** Human skin and depth of penetration of the Fraxel laser with corresponding energy settings. (**E,** Courtesy of Reliant Technologies, Inc., Mountain View, Calif.)

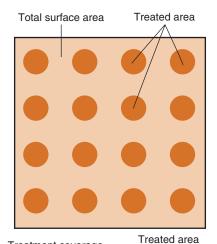

**Figure 49-3 A,** Ablative fractional laser treatment, immediately after treatment. Treatment depth up to 1500 μm. With fully ablated microchannels, necrotic tissue is completely vaporized, with the following results: (1) no residual heating, (2) more comfortable procedure, and (3) faster healing time. **B,** Nonablative fractional treatment, immediately after treatment. Treatment depth up to 1500 μm. Necrotic debris stays in the tissue, with the following results: (1) wide and deep zone of thermal necrosis, (2) more painful procedure, and (3) longer recovery time.

of the dermis or the treatment of leg, truncal, and facial veins. Like ablative lasers, nonablative lasers emit coherent light at wavelengths absorbed by water. This approach has less predictable efficacy compared with ablative laser techniques.

# **Fractional Therapies**

Fractional photothermolysis using the erbium laser has been developed to overcome the disadvantages of conventional ablative and nonablative laser therapies. It produces columns of thermal damage or ablation called foci, or MTZs, ranging between 50 and 150 µm in diameter and located at specific depths from 0 to 550 µm (Fig. 49-3). Treatment time for each pulse (exposure duration) ranges between 3 and 30 milliseconds. The density of treatment corresponds to the inter-MTZ space and is adjustable. Because the MTZs are surrounded by uninjured tissue, keratinocytes have a shorter migration path and healing is much quicker (Fig. 49-4). The technique coagulates both the epidermis and dermis without affecting the stratum corneum, which acts as a natural bandage that protects the tiny wounds as they heal. To improve solar elastosis, scars, and rhytids, a course of treatments, typically three to five, is spaced at least 2 weeks apart. The treatments have fewer and less severe side effects than traditional, nonfractional ablative resurfacing and, with the exception of deep rhytids, the results in terms of skin tone, texture,

**Figure 49-4** Fractionated columns of light versus the traditional laser. With fractional applications, the treated areas are affected by focal columns of light, leaving "dots" of destroyed tissue within the total surface area. In traditional laser ablation, the entire surface area (i.e., the box) would be orange, denoting the affected/ablated area.

Total surface area

Treatment coverage =

dyschromia, and scars are essentially equivalent. More aggressive  $\mathrm{CO}_2$  laser fractional treatment vaporizes tiny columns of tissue entirely and may require fewer treatments than erbium devices, but it causes more downtime because of erythema and even crusting that can last a few days, with a possible higher incidence of postinflammatory hyperpigmentation. The ratio of risk to benefit always must be considered when choosing the appropriate device for the condition to be treated.

Fractional light therapy can be nonablative, using IPL or laser, or ablative with the  $\mathrm{CO}_2$  and erbium laser, with varying degrees of coagulation. Compared with a chemical peel, dermabrasion, or other forms of laser treatment, fractional laser allows the surgeon to customize the surgery more safely, not only to each patient but to each area of the face.

The newer photofacial resurfacing devices include the following:

- Matrix RF (radiofrequency device; Syneron, Inc., Irvine, Calif)
- Erbium (Er:YAG) fractional lasers
  - Lux2940 (Palomar Medical Technologies, Inc., Burlington, Mass)
  - Sciton Profractional (Sciton, Inc., Palo Alto, Calif; Fig. 49-5)
- CO<sub>2</sub> fractional lasers
  - Smartxide DOT (Deka Laser, Florence, Italy)
  - Fraxel re:pair (Solta Medical, Inc., Hayward, Calif)
  - Pixel CO<sub>2</sub> (Alma Lasers, Ltd., Caesarea, Israel)
  - SmartSkin CO<sub>2</sub> (Cynosure, Inc., Westford, Mass)
- Harmony<sup>XL</sup> (pixel laser; multimodality skin rejuvenation; Alma Lasers, Ltd.; see Fig. 49-5)

The types of dermatologic lasers are listed in Box 49-1.

#### Plasma Resurfacing

Skin resurfacing can also be accomplished with a plasma-based device (Rhytec Portrait PSR3; Rhytec, Inc., Waltham, Mass) instead of a laser, although its superiority to laser-based devices remains an open question. Nitrogen plasma energy is delivered to the skin to stimulate skin remodeling while creating a coagulated barrier out of the skin's outer layers that mitigates infection. Studies are lacking to assess its efficacy compared with traditional devices.

## **Intense Pulsed Light**

Intense pulsed-light technology has been increasingly competitive with lasers since the mid-1990s, and owing to enhanced engineering and favorable pricing versus many lasers, IPL devices have proliferated in the skin rejuvenation market. These devices are quickly gaining acceptance in medical offices and spas; although the technology was initially decried as "the poor man's laser" and dismissed as having too many side effects and too little efficacy, the newest generation of devices have proved so popular that even "old guard" companies are adding IPL to their product offerings.

**Figure 49-5** Sciton Profractional laser (**A**) and an Alma Harmony intense pulsed-light device (**B**).

Intense pulsed light has both advantages and disadvantages compared with lasers. Lasers are useful because they permit exquisite control of where and how much one heats the skin. Lasers allow for smaller handpieces, whereas IPL treatment heads house the flash-lamp, cooling apparatus, and high-voltage wires, resulting in a bulkier and heavier handpiece. Like lasers, IPL devices are becoming smaller, more efficient, more powerful, and less expensive. Lasers are more intricate than IPL and therefore more vulnerable to breakdown, resulting in higher purchase costs and more expensive maintenance. Because laser is collimated light, it is less eye-safe than IPL. Collimated light is light whose rays are nearly parallel, and therefore spreads slowly as it propagates. A laser beam delivers more focused energy to the target than IPL and hence is potentially more harmful to the retina. It is imperative, however, to use protective eyewear when operating or undergoing treatment with any light-based device.

Because the three main chromophores in skin (hemoglobin, water, and melanin) have broad absorption peaks, monochromacity is not a prerequisite for selective heating, making IPL an adequate substitution for or, in some instances, even preferable to lasers. When treating sun damage, the targets consist of brown pigmentation (solar lentigines), redness (enlarged capillaries), and water and collagen (textural deterioration). Wavelengths between 515 and 600 nm are optimally absorbed by oxyhemoglobin and melanin, making this spectrum ideal for selective photothermolysis in treating the typical patient with sun-damaged skin (i.e., pigmented areas and redness). IPL devices use flashlamps, computer-controlled power supplies, and bandpass filters to generate light pulses of prescribed duration, intensity, and spectral distribution (see Chapter 48, Lasers and Pulsed-Light Devices: Hair Removal, Fig. 48-1). Flashlamps are high-intensity gas-discharge lamps filled with xenon gas that produce bright light when an electrical current passes through the gas. Electrical energy stored in capacitor banks is converted into optical energy, pulsing the lamps and covering the entire spectrum of light between UV and infrared.

To ensure an even flow of energy, most modern IPL systems use partial-discharge technology. Mirrors surround the xenon flashlamp

# Box 49-1. Lasers Used in Dermatology

- CO<sub>2</sub> laser: The light from these lasers is absorbed by water in the skin; hence, they are used for skin resurfacing, removal of benign skin tumors such as warts, xanthelasma, mucous cysts, cherry angiomas, and leukoplakia, and for surgical cutting.
- Nd:YAG laser: The active medium is a neodymiumdoped yttrium aluminum garnet, producing laser light at a wavelength of 1064 nm. Nd:YAG lasers have slight absorption in melanin and hemoglobin and are used for hair removal, vein treatments, photorejuvenation, acne treatments, and laser skin surgery.
- Q-switched Nd:YAG laser: These lasers have strong absorption in dark tattoo inks, and hence are used in tattoo removal.
- 4. Er:YAG laser: The active medium is an erbium-doped yttrium aluminum garnet, producing laser light at a wavelength of 2940 nm. It is absorbed by water in the skin and is used for skin resurfacing, photorejuvenation, and removal of skin growths.
- 5. Ruby laser: A synthetic ruby crystal (chromium-doped aluminum oxide) is the gain medium, producing laser light at a wavelength of 694 nm. Ruby laser light has very strong absorption in melanin and black and dark blue ink pigments. These lasers are especially useful in tattoo removal, hair removal, and removal of pigmented (dark) skin lesions.

- 6. KTP, or potassium titanyl phosphate, laser: This frequency-doubled Nd:YAG laser with a 532-nm wavelength and absorption by hemoglobin and melanin is used to remove vascular and pigmented skin lesions.
- 7. Alexandrite laser: This Q-switched laser with a 755-nm wavelength is used to remove blue, black, and green tattoos and epidermal and dermal pigmentations (e.g., melasma).
- 8. *Diode laser*: These lasers have varying wavelengths, depending on the color of the target. The absorbing chromophores are melanin and hemoglobin. Diode lasers are used for hair removal, dilated vein treatments, and photorejuvenation.
- 9. *Dye laser*: These lasers contain organic compounds in solution (often rhodamine) as the active medium and have wavelength activity between 400 to 800 nm. The target chromophores are hemoglobin and melanin. Dye lasers are useful in treating vascular lesions and for nonablative skin rejuvenation.
- 10. Excimer laser: Compounds of xenon, krypton, and argon are the active media. These lasers target proteins and water and have wavelengths of 190 to 350 nm. They are useful in the treatment of psoriasis and vitiligo.
- 11. Fractional lasers: These lasers produce microscopic treatment zones and target specific depths in the dermis. These are especially useful for treatment of acne scars, wrinkles, sun damage, and melasma. CO<sub>2</sub> and erbium laser wavelengths are commonly used, and the target chromophore is water.

and the lamp is cooled by water circulating around a quartz envelope, filtering out most of the harmful far-UV output of the lamp. The light output is directed toward the distal end of the handpiece, and a sapphire or quartz block couples the light output to the skin. The normal, unfiltered output of a xenon lamp is between 370 and 1800 nm. Most IPL devices use dichromic filters to transmit a desired range of wavelengths. In other words, they use filters to select the wavelength of light desired to treat the particular entity (e.g., pigment, vessels, collagen). By adjusting the fluence, number of pulses, pulse duration, and the cut-off filter, and considering the patient's particular skin type, various skin targets can be selectively heated to achieve the desired clinical outcome. Most IPL devices have different spot sizes to choose from, facilitating adequate treatment over small or large surface areas.

# INTENSE PULSED-LIGHT PHOTOFACIAL TREATMENT

See Figures 49-6 through 49-8.

The majority of photofacial treatments are performed with IPL devices, and IPL has become a popular treatment in physician offices and spas. IPL is indicated for the treatment of mild to moderate photodamage (type I photorejuvenation).

#### **Indications**

- Solar lentigines
- Chloasma
- Melasma
- Postinflammatory hyperpigmentation
- Actinic lesions
- Telangiectases
- Spider angiomas
- Broken capillaries
- Diffuse erythema and poikiloderma

Skin texture and pore size may also improve from the stimulation of fibroblasts, resulting in collagen production and tightening. The

**Figure 49-6** Before (**A**) and I month after (**B**) a series of five intense pulsed-light treatments with the Vasculight (Lumenis). Improvements in erythema and pigmentation are noted.

**Figure 49-7** Before (**A**) and 2 weeks after (**B**) a single intense pulsed-light treatment with the Vasculight (Lumenis), showing improvement in dyschromia.

final result of a series of photofacial treatments may only be evident a few months later because skin remodeling is a gradual process. Collagen may continue to contract for up to 3 months after treatment.

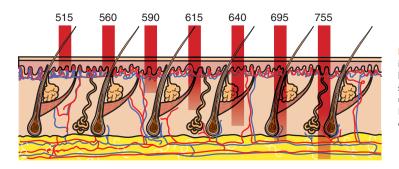

## **Contraindications**

- Patients with darker skin types, such as Fitzpatrick types V and VI, are naturally protected from most UV damage and are generally not good candidates for photorejuvenation, with the possible exception of mild to moderate fractional laser resurfacing to address scars and melasma. They are also much more likely to suffer side effects from light-based treatments because of the high absorption of light by melanin. Practitioners should exercise particular caution because these patients are also more likely to develop keloid scars and hyperpigmentation or hypopigmentation if they sustain a burn wound from overly aggressive treatment.
- A generalized active inflammatory or infectious process of the skin.
- A history of herpes simplex without receiving antiviral prophylaxis (some procedures).
- Photosensitizing medications: If a patient is on Accutane, at least 6
  months should pass after a course is completed before laser or IPL
  is used in order to avoid irreversible skin discoloration.
- Suntan: Patients should wait for a tan to fade before treatments commence to avoid burning the epidermis and risking hypopigmentation, which may take months or longer to heal.

## **Preprocedure Patient Education**

See patient information and consent form online at www.expert-consult.com. In general, IPL treatments should be performed in a series of three to six treatments 2 to 4 weeks apart.

A medical history and clinical examination are required before treatments can commence. The skin should be carefully examined to rule out skin lesions such as actinic keratoses, basal cell carcinoma, squamous cell carcinoma, and melanoma, and such lesions should be treated appropriately before beginning light-based therapies.

**Figure 49-8** Depth of penetration of various cut-off filters used in intense pulsed-light devices for nonablative selective photothermolysis. A wavelength of 515 to 590 nm targets melanin and vascular structures and is used mainly for skin rejuvenation; 640 to 695 nm is used mainly for hair removal; and 755 nm is used for skin tightening. Besides wavelength, fluence and spot size also determine the depth of penetration.

# **Technique**

The patient is placed in a comfortable reclined or supine position; good ambient lighting is needed. The skin must be cleansed and all makeup and skin cream removed before the procedure. Eye protection must be supplied for the patient and can consist of snug fitting metal eye shields or disposable stick-on eye protectors specifically designed for IPL use. The technician must wear appropriate IPL eye protection, and the use of gloves is recommended. Most IPL devices require the application of cool or chilled, clear ultrasound gel to provide a consistent light path and cooling to the skin. Devices that have handpieces with built-in cooling of the light guide require a thin layer of gel; if built-in cooling is absent, a thicker layer of cold gel serves to cool and protect the epidermis. Each manufacturer has specific recommendations for gel use and application related to its particular device design.

The spot size of IPL light guides varies, but the average size is about 2 inches × ¾ inch, whereas laser spot sizes are usually smaller. The handpiece and light guide must be properly cleaned and disinfected, using a medical-grade chemosterilant/high-level disinfectant such as hydrogen peroxide 7%, between treatments. The starting fluence for the first treatment is generally modest and is usually increased with each consecutive treatment. It is good practice to perform two or three "test pulses" in the preauricular area and monitor the treated area for 2 or more minutes to ensure that the chosen energy level does not cause excessive redness, swelling, ecchymosis, or blistering. It should be sufficient to cause end-point pigment darkening and capillary contraction or color changes. Manufacturers will provide suggested treatment settings related to their particular device.

The face is treated in sections that typically consist of each cheek area, from preauricular to midface, with the midface consisting of the nose, upper lip, chin area, and forehead. Care must be taken not to pass over the vermillion of the lips and not to treat closer than ½ inch from the eyebrows and hairline. Because most IPL wavelengths have a strong affinity for melanin and may cause a permanent reduction in darker hair, patients must be made aware of this fact, especially men, who may not want their beard hair decreased by treatment.

It is important to note that the midface is more sensitive than other areas of the face; the patient should be informed of this and that despite the eye protection, they will see bright flashes of light that will not be harmful to their eyesight. Depending on the device, the parameters, and the protocol, one or more passes may be made of the face or certain areas using the same or different cut-off filters. When the treatment has been completed, the gel must be removed, the skin gently cleansed, and a soothing aloe-based gel or protective moisturizing cream applied. The treatments are repeated every 2 to 3 weeks, with a total of three to six treatments being typical. Herpes simplex prophylaxis should be prescribed when laser or IPL devices are used in treating the perioral region for patients with a past history of herpes simplex type 1 infection. Valacyclovir 2 g 1 hour before the procedure and 2 g 12 hours after the first dose is effective.

Maintenance IPL treatments can be performed every 3 to 4 months, choosing parameters based on any skin pigmentary changes in the interim. Other areas of the body can be treated, including the neck, décolleté area, arms, hands, back, and legs. The fee for the procedure is calculated by either area or the number of pulses used.

# **Postprocedure Patient Education**

Patients must be instructed to avoid sun exposure and use a good-quality, UVA/UVB broad-spectrum sunscreen (SPF 15 to 30) daily. If a patient has acquired a tan between treatments, any further treatments should be postponed until the tan has faded. Appropriate skin care is beneficial for patients undergoing a series of photofacial treatments. Exfoliation of the stratum corneum with microdermabrasion or gentle chemical peels can assist in removing surface pigmentation between IPL treatments, and using a daily moisturizer can treat dry skin caused by increased skin turnover after IPL treatment. Patients should also be made aware that maintenance treatments will be required every 3 to 4 months to avoid a gradual return to baseline. Patients should be educated regarding the dangers of UV light exposure and the continued use of a sunscreen because this information will help them prolong the beneficial effects of their photofacial treatments.

#### **Complications**

Surface cooling of the skin is extremely important with IPL to avoid side effects such as burns that can lead to pain, blisters, infection, scars, and hyperpigmentation, especially on darker skin types. Newer IPL devices have built-in contact cooling, allowing the light guide to be placed directly on the skin, achieving effective cooling and precisely duplicable results with each pulse. Other cooling methods include cold ultrasound gel, cold air devices, and cryogen spray.

#### **Common Errors**

- Single, aggressive treatments can yield impressive results, especially for superficial pigmentation; however, this approach is painful, the risk of short-term side effects is higher, and most patients desire a no-downtime treatment with an acceptable comfort level. Achieving a no-downtime treatment regimen requires starting treatments at a modest fluence and incrementally increasing the energy in subsequent treatments toward a target level.
- Care must be taken not to use too much pressure when treating capillaries because excessive pressure will result in blanching, and the target will be lost and not effectively treated.
- Some IPL devices rely on the use of cold ultrasound gel to be placed on the skin for cooling and "drifting" the light guide in the gel just above the skin surface. Although the technique is effective, the skill and experience of the operator are important in achieving consistent results.

# **Adjunctive Treatments**

#### 5-Aminolevulinic Acid (Levulan)

An adjunctive treatment that complements IPL extremely well is the use of the photosensitizing agent 5-aminolevulinic acid (Levulan, DUSA Pharmaceuticals, Inc., Wilmington, Del) to broaden the overall benefits and improve the end results achieved with photofacial treatments. The treatment is known as photodynamic therapy (also see Chapter 60, Photodynamic Therapy). 5-Aminolevulinic acid is approved for the treatment of actinic keratoses. It is used in the treatment of nonmelanoma skin cancer and of systemic cancers. It is also applied "off-label" with excellent results for the treatment of acne. Levulan is prepared by breaking chambers in a vial. It is then applied directly to skin that has been prepared with microdermabrasion, or by acetone or alcohol scrub, to break down the skin's lipid barrier. The material is allowed to be absorbed over time, which increases the effectiveness of light therapy. The interval between application and the start of IPL treatment is referred to as the incubation time.

When combined with IPL, short incubation times between 15 minutes and 1 hour can be used with good clinical response. Improved reduction of brown and red pigments, textural improvement, and pore minimization can be expected with this approach. Patients *must* avoid any sunlight or bright indoor light exposure to the treated skin for 24 hours after treatment to minimize erythema and avoid burns. Some erythema, flaking, swelling, or peeling can be expected with 5-aminolevulinic acid treatment.

#### Retinoids

Topical retinoids (i.e., tretinoin and isotretinoin) are another adjunctive treatment that has been shown to improve the outcome of IPL treatments. Patients should be motivated and prepared for possible erythema and dry, flaking skin with the use of topical retinoids. Patients should start using retinoids at least 2 weeks before commencing IPL, discontinue application 2 days before IPL, and resume use a day after treatment. Because retinoids are photosensitizing, increased flushing and some downtime may occur when they are used in conjunction with IPL to treat sun damage. For this reason, retinoids are reserved for more severe sun damage. Microdermabrasion is never used when a patient is using retinoids because of increased skin fragility and should be considered only after the retinoid has been discontinued for at least 1 month. Waxing should also be avoided when retinoids are being used. Retinoids alone have beneficial effects on sun-damaged skin, improving texture and dyschromia with consistent use, and may be used over the long term to reduce the frequency of maintenance IPL treatments.

### **Nonfacial Treatments**

Other body areas can be treated with IPL with equal efficacy, including the neck, chest, arms, and legs. Fluences should be lowered when treating the neck and décolleté areas and always adapted to the particular skin area color. With years of sun damage, more exposed areas my have increased background melanin than less exposed areas and should be treated accordingly.

# **CONCLUSION**

Photofacial treatments have become an accepted method of improving the appearance of the skin, especially photodamaged and aging skin. Many modalities are available, and it is up to the practitioner to decide on the most appropriate treatment to address the patient's concerns. In some cases, combination treatments may be required. The patient's expectations, budget, and clinical concerns must be considered when deciding on the appropriate treatment method. IPL has become the most common and popular treatment option for photodamaged skin because of its good safety profile, minimal downtime, low cost, and excellent results.

When IPL is used for the appropriate candidate, results can be dramatic and very pleasing for the patient as well as rewarding for the practitioner. The technology has seen significant advances in recent years, overcoming many of the initial barriers and objections to its use to such an extent that in some cases it is now preferred over laser treatment. For the cosmetic dermatology practitioner, IPL is a modality to combine with other, traditional laser devices to satisfy the demands of patients and allow for a comprehensive armamentarium of light-based skin treatment devices to be available to address various skin concerns.

# Selected IPL manufacturers

Aesthera Corp.

Alma Lasers, Ltd.

Cynosure, Inc.

Lumenis Palomar Medical Technologies, Inc. Sciton, Inc. Syneron, Inc.

**AUTHOR'S NOTE:** Many different manufacturers produce IPL devices today, some of which are inexpensive and of low power, often purchased by spas and salons. High-quality equipment, supported by reputable clinical studies, ensures high-quality treatment, the best results, and high-quality support by the manufacturer. Proper research, discussion with peers, and attendance at national and international laser conferences, such as the ASLMS (American Society of Laser Medicine and Surgery), are strongly recommended before any purchase is made.

# LASERS AND PULSED-LIGHT DEVICES: ACNE

Renier van Aardt

Acne vulgaris is a common chronic disease affecting the pilosebaceous follicle of the face, neck, back, chest, and other areas of the body. It affects 40 million American adolescents and 25 million adults. At least 50% of adults admit to having suffered with some degree of acne in their lifetime. In the past, people have treated it many different ways, with everything from handfuls of vervain (a flowering herb) to bloodletting (India). Even arsenic and x-rays were used with little benefit and considerable risk because people were willing to try anything for even minor improvements. Given the prevalence and number of patients who suffer from refractory acne, alternatives to existing treatments are constantly sought. Acne vulgaris is a disease that not only causes physical blemishes but has major psychological effects on its sufferers, including social withdrawal, clinical depression, and suicide. In recent years, the use of laser- and light-based devices has had a significant impact on our ability to manage acne.

#### CLINICAL APPEARANCE AND GRADING

Acne has been classified from grade 1 to grade 4 depending on its severity. Variations include minor blackheads and whiteheads and clogged pores (grade 1) that can become infected and inflamed (grade 2), leading to large red papules and pustules (grade 3) and cysts and nodules (grade 4). Lesions are often "popped" or picked by the patient. With the larger lesions, scarring is often the result. The usual type of depressed scarring can last throughout a person's life, and can become an extremely noticeable facial imperfection. Scars can be erythematous, irregular, textured lesions, enlarged pores, or deep icepick and cratered lesions. Treatment is primarily directed at reducing inflammation and preventing scars. However, light-based technologies also make scar reduction and skin remodeling possible to improve appearance.

# **INTERNAL CAUSES**

There are many contributing factors to the severity of acne, but no clear single cause has been identified. Acne develops as the patient progresses through puberty and the sebaceous glands grow and increase their sebum secretion. Acne is more prevalent and severe in males because of the increased production of *testosterone* during puberty. Adult-onset acne in women may be attributed to cyclical variations in sex hormones, with an increase in androgenic hormone levels resulting in an increase in sebum production. This increase in sebum, coupled with the keratinization of the hair follicle, causes occlusion of the ducts and in turn the formation of comedones.

There is a correlation between the *depth of the hair follicle* and the size of the lesion. The deeper the follicle, the deeper the occlusion, which in turn results in a larger lesion.

The bacterium *Propionibacterium acnes* causes inflammation either because of an immune system reaction, inflammatory enzymes from the bacteria, or a combination of the two. *P. acnes* is a normal colonizer of the sebaceous follicles; it is a gram-positive, microaerophilic bacterium that, as part of its normal metabolic and reproductive processes, produces and accumulates endogenous porphyrins, namely protoporphyrin, uroporphyrin, and coproporphyrin III. Porphyrins can be visualized using a Wood's lamp or digital fluorescence photography because they absorb light energy at the near-ultraviolet and blue-light spectrum. This unique attribute of the bacterium lends to the therapeutic effects of some light-based treatments.

#### **EXTERNAL CAUSES**

External factors vary from patient to patient, but there are several factors that can affect the severity of acne. *Diet* will affect each patient individually, and although dairy products seem to cause problems in women, no other real universal dietary factors have been identified. *Thick makeup, hair spray, greasy hair gels,* and *hats, sweat bands,* or *athletic helmets* are all external factors that contribute to the severity of acne because of the combination of mechanical or chemical irritation, oil gland occlusion, and bacterial colonization. In some work environments, exposure to industrial products like cutting oils may produce acne. In addition, *inadequate cleansing* contributes to the development of acne. In all cases, the external factors aggravate acne, but are not the root cause of the disease.

Patients should be advised not to rub, scratch, pick, or squeeze their skin because *mechanical irritation* can aggravate acne and lead to scarring. Careful and controlled extraction of comedones by a trained aesthetician or nurse after steaming and appropriate skin preparation may be beneficial. Some *drugs* can cause or worsen acne, including iodides, bromides, and oral or injected steroids. A proper skin care regime is helpful to minimize the severity of acne by removing impurities and irritants.

# **TREATMENT OPTIONS**

Because the pathogenesis of acne involves four factors (hypercornification of the pilosebaceous duct, increased sebum production, colonization by *P. acnes*, and the development of inflammation), a stepwise and systematic approach to treatment is best. Because acne is a chronic disease, its treatment is an ongoing process that requires educating the patient as well as patience on the part of both the patient and the clinician, to allow each step in the treatment process to take effect. Treatments aimed at clearance of *P. acnes* alone generally provide short-lived improvement; therefore, combination therapy is recommended (Table 50-1).

The first universal step is appropriate skin care. Cleansing the skin seems to help all patients, if only slightly, but acne is not directly

TABLE 50-1 Treatment Options in Acne Management

Gentle skin care and extraction of comedones Topical retinoids Exfoliation: peels and/or microdermabrasion	Gentle skin care and extraction of comedones Blue light Topical retinoids Benzoyl peroxide Topical antibiotics Exfoliation: peels (salicylic/glycolic) and/or microdermabrasion Photodynamic therapy	Gentle skin care Blue light and red light Topical retinoids Benzoyl peroxide Systemic and/or topical antibiotics Hormonal therapy Exfoliation: peels (salicylic/glycolic) and/or microdermabrasion IPL and photodynamic therapy	Gentle skin care Blue light and red light Systemic antibiotics Hormonal therapy IPL (not with tretinoin) and photodynamic therapy Systemic isotretinoin	Gentle anti-inflammatory skin care Topical antibiotics and/or systemic tetracyclines Glycolic acid peels IPL and photodynamic therapy Avoid triggers	

IPL, intense pulsed light.

caused by dirt. Cleansers have an antibacterial effect and may reduce bacterial colony counts. Toners may be helpful in restoring the pH balance of the skin after cleansing to an acidic state. Using gentle exfoliation such as microdermabrasion or glycolic facials may be helpful to remove excessive keratin from the epidermis and open pores, allowing sebum to drain freely. Overscrubbing is not recommended because the skin becomes dry, damaged, and inflamed and as a result can become less receptive to topical products. Abrasive home scrubs are therefore not recommended for acne-prone skin. A gentle cleanser is all that is necessary to cleanse the skin properly. Moisturizers that are noncomedogenic are helpful to prevent skin dehydration and to counteract the drying effect of many other active ingredients, such as benzoyl peroxide. The most commonly used cleansers are available over-the-counter and include Clearasil and PHisoderm, but aesthetic physicians' offices and spas also have a variety of excellent brands available to their clientele.

As with many other cosmetic treatments, combination therapy is the best approach to treating acne, which brings us to the *second step of treatment*. Using topical products, such as *topical retinoids*, maximizes the effect that an intense pulsed-light (IPL) treatment will have on the acne. Retinoids are comedolytic and act on the keratinization of the hair follicle. They are therefore beneficial for acne grades 1 and 2 where comedones predominate. Differin (adapalene) is the least irritating, but others, such as Retin-A (tretinoin) or Tazorac (tazarotene), may also be used. There are many over-the-counter retinoid creams on the market, but these do not usually deliver consistent levels of retinoid to the dermis.

Retinoids result in a decrease in sebaceous duct occlusion, preventing oil from accumulating in the sebaceous glands and creating a favorable habitat for bacterial colonization. Inflammatory acne, on the other hand, responds better to topical antibiotics and photodynamic therapy (PDT; Fig. 50-1). Preparations that combine antibiotics like clindamycin with benzoyl peroxide are available for better efficacy than single antibiotics alone. In addition, blue light (415-nm wavelength) has excellent antibacterial properties against porphyrin-producing bacteria because porphyrins release singlet oxygen when activated by this wavelength of light. Singlet oxygen is toxic to the bacteria (see Chapter 60, Photodynamic Therapy).

Hormonal therapy is a useful adjunct in the treatment of acne in female patients. The onset of acne is triggered by the increased production of androgens. Oral contraceptives inhibit ovulation, thereby preventing androgen production by the ovaries. Lower serum androgen levels reduce sebum secretion, which consequentially exerts an antiacne effect. The mean reduction in total facial acne lesions with the use of drospirenone and cyproterone acetate (components of birth control pills) has been shown to be 62% and 59%, respectively. Other contraceptives with antiacne effects include norgestimate and levonorgestrel.

Oral antibiotics and isotretinoin (Accutane) constitute the next level of traditional therapy. However, the availability of lasers, IPL devices, and PDT now provides excellent treatment options that avoid possible systemic side effects, leaving oral treatment as an alternative for severe and unusually refractive cases. Intralesional steroids are infrequently used and are more appropriate for early nodular lesions; they should not be a standard treatment for acne. Newer devices that extract comedones in the course of IPL treatment are excellent for grades 2 and 3 acne. Gently extracting large comedones and draining superficial cysts may be helpful when providing full-face treatments such as IPL and PDT. Strong pressure should never be applied to avoid spreading infection. Oral antibiotics such as minocycline are very effective in treating acute flare-ups of papulopustular acne. Oral antibiotics also reduce the severity of acne in conjunction with or before the initiation of light-based therapy. Combining tetracyclines with light therapy is a relative contraindication because the skin is more photosensitive, but in my experience the increased post-treatment erythema is worth the benefit. Patients need to be informed of the possible side effects.

#### Rosacea

Although rosacea is a different disease from acne vulgaris, it warrants discussion here because of the many similarities between the two, including an inflammatory component and small papules and pustules. When treating rosacea, skin care should be restricted to mild, hypoallergenic products. Prescription metronidazole preparations such as Rosasol and Metrogel are effective at controlling the

**Figure 50-1** Treatment of inflammatory acne with scars. Five intense pulsed-light treatments were performed with the Vasculight (Lumenis, Yokneam, Israel) SR handpiece combined with three photodynamic therapy treatments with incubation periods lasting 30 to 90 minutes. **A,** Before treatment. **B,** After treatment.

**Figure 50-2** Treatment of refractory rosacea acne with five intense pulsed-light treatments with the Vasculight and three photodynamic therapy treatments with incubation periods of 60 to 120 minutes. **A,** Before treatment. **B,** After treatment.

disease activity, and IPL and PDT treatments can be highly effective in reversing erythema, telangiectasia, and the activity of the disease (Fig. 50-2).

# Blue Light and Red Light Therapy

Approximately 70% of patients report improvement of their acne after sunlight exposure. In vivo studies, however, have provided insufficient evidence to justify the use of ultraviolet A and B as antiacne treatment, especially given their potential carcinogenicity. Because the strongest porphyrin photoexcitation band that produces singlet oxygen lies between 407 and 420 nm, irradiation of *P. acnes* with blue light leads to predictable bacterial destruction. Studies have shown a mean acne lesion reduction of 64% for papulopustular acne in a treatment course of two 15-minute sessions per week over 5 weeks. Various devices are available, such as the Clearlight, the Blu-U, and 410-nm IPL devices. The treatments are painless and have no side effects (Fig. 50-3).

**Figure 50-3** Blue light sessions combined with extractions and skin care (**A** and **B**). Before (**C**) and after (**D**) a 6-week course of twice-weekly treatments.

Although *blue light* has the strongest porphyrin photoexcitation ability, it is limited by its depth of penetration in skin. *Red light*, although a less effective photoexciting wavelength, has an increased depth of penetration in human skin and may also induce anti-inflammatory effects by stimulating cytokine release from macrophages. Improvements as high as 76% have been achieved in combined blue and red light studies, perhaps because of a synergistic effect of these wavelengths.

# **Photodynamic Therapy**

Photodynamic therapy (see also Chapter 60, Photodynamic Therapy) refers to the topical application of D-aminolevulinic acid (ALA; e.g., Levulan) to the skin, which, when preferentially absorbed by pilosebaceous units, is metabolized through the heme synthesis pathway to produce protoporphyrin IX. PDT has been widely used for the treatment of a variety of skin diseases, including nonmelanoma skin cancer, actinic keratoses, warts, psoriasis, cutaneous T-cell lymphoma, and acne vulgaris.

When protoporphyrin IX is photoactivated by the appropriate wavelengths of light (intense pulsed light [IPL], pulse light, or blue light), singlet oxygen and free radicals are produced with cytotoxic effects. Not only is P. acnes destroyed, but the pilosebaceous unit is damaged or destroyed. ALA application time, also referred to as the incubation period, can vary between 15 and 120 minutes. Red light, blue light, IPL, diode laser, pulsed dye laser, and light-emitting diode (LED) sources have all been shown to be effective in activating protoporphyrin IX. Studies have shown a decrease in acne lesion counts that persists from 10 to 20 months after one to four treatments. Typically, three treatments are performed at 2- to 4-week intervals to achieve a remission of this duration. PDT results in a temporary reduction in skin oiliness, improvement in acne severity. and a cosmetic improvement of the skin with textural improvement and a reduction in sun damage and pore size. Cosmetic improvement of the skin is maximized when IPL parameters for skin rejuvenation are used at a moderate fluence. Possible side effects include initial burning discomfort, self-limiting crusting, erythema, mild edema, and hyperpigmentation. The side effects are reduced with short incubation periods and are self-limiting. Patients must stay out of the sun and bright rooms for a minimum of 24 hours after ALA is applied.

# **Intense Pulsed-Light Therapy**

Intense pulsed light is a broadband light source that uses multiple wavelengths typically produced by a xenon flash-lamp, coupled with light filters to select specific bands of wavelengths to treat certain conditions. With acne, wavelengths are used that are highly absorbed into the sebum, the bacteria that are in the lesions, and the sebaceous glands (400 to 600 nm). These systems, such as the ClearTouch or Palomar Starlux with the LuxV handpiece, can be used on all skin types. The Lume 1 (Lumenis) is faster and can be used on all but the darkest skin types). Caution must be exercised when treating darker skin types because these wavelengths have an extremely high melanin absorption coefficient, so the risk of burning is high without proper settings, effective epidermal cooling, and testing. The broad range of emitted wavelengths covers the peak absorption of endogenous porphyrins produced by P. acnes, as well as that of hemoglobin in blood vessels close to the inflamed acne lesions, leading to both antibacterial and anti-inflammatory effects (Fig. 50-4).

Patients must be protected from any possible sun exposure before treatment because increased skin pigment (tanning) will increase the risk of epidermal burning from the artificial light sources. A very small amount of sun exposure can alter the pigment of the skin, restricting the technician's ability to treat at optimal settings. Self-tanning creams are also contraindicated because any darkening of the skin that increases absorption of light energy where it is not

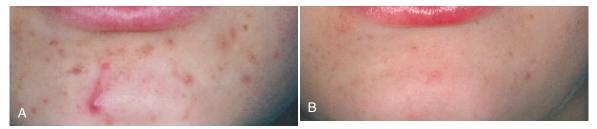

Figure 50-4 Treatment of recalcitrant acne on the chin. The patient received 2 weeks of twice-weekly treatments with the LuxV handpiece (Palomar Medical Technologies, Burlington, Mass). A, Before treatment. B, After treatment.

desired will restrict the amount of power that can be safely used. Areas of higher melanin concentration and areas of more sensitive skin should be evaluated and treated accordingly. Pretreatment of the skin with topical hydroquinone 4% twice a day for 2 to 4 weeks for patients with Fitzpatrick skin type 4 or higher will reduce the incidence of hyperpigmentation after laser and IPL treatments.

Treatment with light-based technology incorporates the ability to tailor both the pulse duration and the fluence energy used. Contact cooling before, during, and after the light pulse is also important. Tailoring pulse duration means altering the duration of light being emitted from the flash-lamp in milliseconds. The delay between pulses allows some cooling of surrounding tissue while target chromophores absorb additional energy with the second, shorter pulse. Cooling of the epidermis allows the user to deliver a larger amount of energy to the target and also reach deeper into the skin, while protecting the superficial layers of the skin. Some additional cooling may be necessary after treatment, both for comfort and to prevent blistering (e.g., ice pads). Using these principles, the initial treatment settings are often 100-msec pulse duration with fluences of 10 to 14 J/cm<sup>2</sup>, followed by a second pass using a 20-msec pulse with fluences of 8 to 12 J/cm<sup>2</sup>. Subsequent treatments will have the same pulse durations, but with increasing fluence. The first pulse penetrates deeper and allows for a longer heating time to affect the cysts and glands, whereas the second pass attacks the more superficial lesions. Most patients notice improvement with five to six treatments. If the fluence is not increased throughout the course of the treatments, results may not meet expectations. The treatment will cause some discomfort, and some redness is to be expected, but it typically clears within hours.

Treatments should be conducted at 2- to 3-week intervals for teenagers because their flare-ups seem to occur within this time frame, whereas adults respond better to monthly treatments. When treatment intervals are too short, flare-ups may occur; however, too long of an interval between treatments will also diminish the cumulative effect of treatments and the ultimate outcome.

With regard to *complications*, as stated earlier, there is a large amount of melanin absorption at these wavelengths, and therefore patients should be advised that permanent hair reduction may occur in the treated areas. Men are required to shave before treatment on the face, and some pain is to be expected in these areas. There can be lateral spread of the effect owing to diffusion of light in the skin, so if trying to avoid a hairline or eyebrow, stay at least 2 cm away from it to ensure that no thermal damage to the hair bulb or stem cells occurs.

"Major" complications include superficial blisters and burns. These are ultimately caused by overtreatment, too much sun exposure, or patients not following post-treatment instructions. Most burns and blisters can be treated with a class I steroid (clobetasol cream), and blisters can be treated with antibiotic/healing creams. Most burns resolve spontaneously within 2 months; however, hypopigmentation can still be seen after 8 to 12 months on some darker-skinned patients.

After treatment, in addition to immediate cooling with a cold pack, patients are told to limit sun exposure, use a noncomedogenic moisturizer that includes a sunscreen, and avoid external heating

factors that could create an adverse reaction. Most patients are able to continue their combination oral or topical therapies during the treatment course, including tetracycline antibiotics. Combination therapy increases the treatment success rate. Some erythema secondary to the thermal damage is to be expected. This can be treated by short-term use of an over-the-counter hydrocortisone cream, which will not affect the treatment or cause further breakouts. LEDs such as the Gentlewaves (590-nm wavelength) can be used because LEDs are proven to aid the body in the thermal healing response.

# **Laser Therapy**

Lasers with wavelengths used to treat vascular lesions and superficial pigmented lesions can also be used to treat acne. These wavelengths also act through photoactivation of bacterial porphyrins as well as potentially causing nonspecific thermal injury to sebaceous glands. Devices such as the Aura, a potassium titanyl phosphate (KTP) laser, and the NLite System, a pulsed dye laser, have been shown to provide a reduction in acne severity. Studies with as few as one treatment to biweekly treatments for 2 weeks reduced acne by 39% to 50%. Results were found to be more effective in combination with topical therapy than with lasers alone.

Infrared lasers have recently become one of the most effective available acne treatments because of their depth of penetration into the dermis. Experience with isotretinoin use has shown shrinkage of sebaceous glands and marked reduction of sebum production during treatment. Although sebum production returns to normal after cessation of treatment, many patients remain clear of acne, leading to the hypothesis that a temporary effect on sebaceous glands may be adequate to induce long-term acne clearance. With infrared lasers, the target chromophore is water, which is the dominant chromophore in sebaceous glands. The laser produces an injury zone in the dermal layer where sebaceous glands are located and in theory causes enough injury to arrest overproduction of sebum, thereby eliminating acne.

Both 1450-nm and 1540-nm lasers have been studied in trials. Initial biopsies confirmed thermal coagulation of the sebaceous gland, but biopsies at 2 and 6 months revealed no long-term alteration of the skin. Studies combining pulsed dye laser with infrared laser show synergistic effects, suggesting that infrared laser may have clinical use as a primary or adjunctive acne treatment in patients requiring an alternative to more traditional methods of treatment. Side effects are transient and local, including erythema and discomfort during treatment, without any delayed adverse effects.

# **Radiofrequency**

Although radiofrequency is not a light-based technology, it has a similar effect on the sebaceous unit as laser by producing thermal injury to the dermis, including the sebaceous gland. The Therma-Cool system has been studied and shows encouraging results in reducing acne and improving acne scarring, although the study size was small with limited follow-up, underscoring the need for larger studies with longer follow-up.

#### **CONCLUSION**

A proper history and physical examination with accurate diagnosis are imperative before treatment of acne commences. A stepwise approach and establishing realistic expectations are important. Patients need to understand the chronic nature of the disease and the possibility that acne will be refractory to treatment. Combination therapy remains the best approach in the treatment of acne.

Comedonal acne is best managed with skin care that includes appropriate exfoliation and topical retinoids. If multiple lesions are inflamed and infected, benzoyl peroxide and topical or oral antibiotics must be prescribed along with skin care to reduce the infection. Blue light, IPL, and PDT can be added for more severe cases.

Nodulocystic acne is unlikely to respond to topical therapy and, if the severity warrants, is best treated with oral antibiotics and PDT in combination with IPL and blue light or isotretinoin (Accutane). Unfortunately, recent continued negative publicity and its correlation with depression and suicide, as well as documented birth defects, may lead to Accutane's eventual recall from the U.S. market by the Food and Drug Administration.

The use of light-based technology has greatly increased the treatment success rate for acne. It may be considered after oral and topical therapy failure in patients with inflammatory acne without scarring, or in conjunction with current therapies as part of a first-line of therapy in patients presenting with both active acne and acne scars. However, cost, discomfort, erythema, multiple office visits, and complications are potential downsides to laser and other light-based therapies.

These newer treatments provide an attractive alternative for noncompliant patients and are free of complications such as antibiotic resistance and teratogenic side effect profiles. With continued technological advances in the ability to selectively target *P. acnes* and sebaceous glands, a new frontier of acne treatment is evolving, providing patients with safer and more effective treatment choices for one of the most prevalent and distressing skin conditions.

# LASERS AND PULSED-LIGHT DEVICES: SKIN TIGHTENING

Gregory Costello

Advances in aesthetic and anti-aging medicine have led to treatments that were not available just a few decades ago. A multitude of options other than surgical intervention are now available to the patient who wishes to improve his or her appearance. The trend in aesthetic medicine has increasingly shifted from the concept of painful, long surgical recovery to multiple "minimal down time" procedures with little to no pain. This is especially true regarding the topic of skin tightening.

In the past, the concept of skin versus muscle laxity was irrelevant in terms of treatment because in either case the only treatment was surgical. However, with the advent of novel technologies that cause contraction, synthesis, and remodeling of collagen, "loose skin" can be addressed through noninvasive means. Laxity below the eyes, lowering of the brows, prominence of nasolabial folds, and formation of "jowls," among a multitude of other skin laxity issues, can be easily improved without painful surgery, long recovery times, or the risk of anesthesia.

Some types of sagging were and are still treated with surgery, such as an abdominoplasty (Fig. 51-1). This procedure is painful and requires general anesthesia. In addition, the procedure is costly, requires significant down time for recovery, and often leaves an unsightly scar.

This chapter focuses on the latest technologies developed specifically for tightening lax and sagging skin, which in turn reduces wrinkles and improves skin surface irregularities (Figs. 51-2 and 51-3). The latest technologies include intense pulsed light (IPL), radiofrequency (RF), and laser modalities to achieve a similar goal of dermal heating to produce changes in skins. (Also see Chapter 52, Nonablative Radiowave Skin Tightening with the Ellman S5 Surgitron [The Pelleve Procedure].) Most of these modalities show some immediate short-term results owing to temporary protein contraction; however, because of the stimulation of collagen formation, maximum results, which are also longer lasting, require up to 8 months to complete the remodeling process.

# SKIN STRUCTURE AND BREAKDOWN

As we age, our skin's structure deteriorates as a result of sun exposure, dietary habits, and natural processes. As the collagen in the skin breaks down, the skin's tightness and general elasticity decreases, causing a sagging or loose appearance. This tissue breakdown occurs at a depth of 3 to 5 mm in the dermis.

## **TREATMENT EVOLUTION**

The new technology that has evolved from older treatments involves passing certain types of light or current through the top layers of skin, leaving them undamaged but affecting a specific target deeper in the dermis, which in turn stimulates the production of "good" collagen. These treatments are mostly quite noninvasive and, in

most cases, involve very little pain. They do involve multiple treatments, and the results are noticeable over time.

#### **LIGHT-BASED TECHNOLOGY**

In recent years, many systems have been developed using light to target the condition of loose skin. These systems use various wavelengths and different types of technology. In principle, light penetrates deep into the skin where it is absorbed by water and converted to heat energy. The thermal conversion then stimulates fibroblasts to produce new collagen. Some of the original systems, such as the CoolTouch (Roseville, Calif) system, used the 1320-nm neodymium-doped yttrium-aluminum garnet (Nd-YAG) wavelength. The 1440-nm Nd-YAG wavelength has also been used, but the results have been only slightly better than those with the 1320-nm systems. Good results have also been achieved with the use of IPL technology to deliver specified wavelength bands for a more efficient heating process. IPL technology uses several wavelengths banded together by light cut-off filters to specifically target certain chromophores in the skin. In the case of skin tightening, the target chromophore is water. Accordingly, for the treatments to be effective, the system must use wavelengths that are well absorbed by water.

# **Infrared Light**

Infrared laser technology can be used to target water as a chromophore for photothermolysis. There are many examples of infrared technologies, both ablative and nonablative, that can be used to promote collagen growth in the dermis. The Cutera (Brisbane, Calif) 1064-nm Nd-YAG laser targets microvasculature to produce subdermal heating using high peak energies delivered through microsecond pulses. This gentle heating of the skin causes type I collagen formation, resulting in improvement in skin firmness and texture. Type I collagen is the most abundant type of collagen in the body and is found in blood vessels, multiple organs, tendons, and bone, as well as in skin. The proportion of type I collagen increases when tissue repair or healing occurs.

There are other wavelengths in the infrared spectrum that are surface ablative and promote collagen growth by means of deep dermal heating. Use of these lasers improves surface defects in the skin (e.g., roughness, sun damage, rhytids) as well as promotes collagen growth. The 2790-nm yttrium–scandium–gallium garnet (YSSG) laser (Pearl Laser; Cutera) uses water as a chromophore, causing vaporization of approximately 10 to 30  $\mu m$  of epidermal tissue and coagulation of an additional 20 to 60  $\mu m$  of tissue. Below this layer of coagulation, the tissue is heated. It is in this heated subcoagulation region where collagen stimulation occurs. The coagulated tissue acts as an occlusive dressing that quickly peels off, leaving behind a layer of skin where the collagen remodeling occurs.

**Figure 51-1 A,** Preoperative photograph showing laxity of the abdominal skin. **B,** Same patient 3 months after treatment. (Courtesy of Palomar Medical Technologies, Inc., Burlington, Mass.)

The most widely used parameters for this treatment are between 1.0 and 3.5 J/cm<sup>2</sup>, with a pulse width of 0.3 to 0.5 msec. Maximal dermal heating occurs with a higher pulse width with this procedure.

# Fractionated Infrared Light

The use of fractional light delivery with infrared light allows for a higher fluence, resulting in a deeper thermal effect and thus deeper tightening. The idea of fractional energy delivery, which has been made popular recently by the Reliant Fraxel (Solta Medical, Hayward, Calif) and Palomar Lux IR (Palomar Medical Technologies, Burlington, Mass) systems, involves controlled thermal damage. The concept centers on the principle of using microlenses to focus light to create a significant amount of thermal damage in one column while leaving the surrounding tissue relatively undamaged. This stimulates the skin's normal healing response, including fibroblast activity that promotes new collagen production. In the case of the Palomar Lux IR fractional system, fractional delivery is combined with optimum wavelength selection to allow for deep thermal injury with minimal pain and risk. Cooling is absolutely necessary because these wavelengths are all very highly absorbed by water, and at the fluencies that are being used a burn is likely without proper cooling. This system is equipped with contact sensors, which allow the system to fire only if proper contact is achieved. This ensures that the skin is adequately cooled.

# **Intense Pulsed Light**

Intense pulsed-light technology, in the infrared wavelengths, uses a spectrum of wavelengths to achieve collagen production through fibroblast stimulation. The Cutera Titan XL uses flash lamp technology in the 1100- to 1800-nm wavelengths, where water is the dominant chromophore. The challenge in IPL technology has always been to provide enough energy to the desired target without causing thermal damage to the surface tissue. The Titan XL overcomes this risk through a cycle of cooling before and after the delivery of energy to the desired target. The treatment area is covered with a thin layer of gel and the  $3 \times 1$ -cm IPL handpiece crystal is placed directly in contact with the skin. One second of cooling is followed by the

delivery of heat at the selected fluence, followed by 2 more seconds of cooling. Both the cooling and delivery of energy take place through the contact crystal and are preprogrammed to occur automatically without having to lift the handpiece from contact with the skin. This automated cycle allows for the delivery of high amounts of energy deep into the skin while protecting the surface from visible damage.

# **RADIOFREQUENCY**

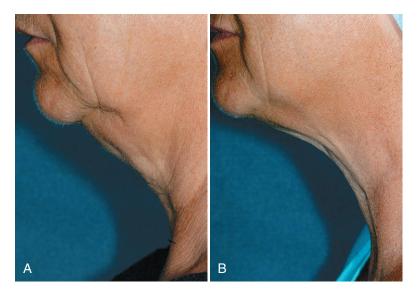

Radiofrequency, unlike light-based technologies that operate based on absorption coefficients, is based on passing an RF current deep into the skin that is designed to denature collagen deeper in the skin while leaving the top layer undamaged. This causes immediate tightening and thermal damage, which stimulates new collagen growth. The thermal effect is generated by the tissue's natural resistance to the movement of ions within an RF field.

The ThermaCool TC system from Thermage (Solta Medical) is an example of a monopolar RF technology. This system uses a capacitive coupling membrane to couple the RF to the skin. A grounding plate is attached to the patient to dissipate the current, and the RF generator is then turned on. This type of delivery allows for deep penetration by the RF and, as a result, much better heating than that obtained with RF bipolar electrodes. Monopolar delivery of RF causes excellent volumetric tissue heating. Monopolar RF treatments are moderately painful and do pose a risk for scarring and burns when not operated correctly.

Another approach to skin tightening using RF technology is the addition of IPL. The ReFirme ST from Syneron (Irvine, Calif) uses pulses of infrared light in the 700- to 2000-nm wavelength range simultaneously with bipolar RF. The pulse of infrared light uses melanin and hemoglobin as chromophores, thus heating the dermis. The heating effect creates a path of optimal electrical conductivity or lower impedence. Because electricity prefers the path of lowest impedence, the electrical bipolar RF energy is concentrated at the target site preheated by the optical energy. Contact cooling at the treatment site minimizes electrical conduction to the epidermis and allows most of the energy to penetrate into deeper parts of the dermis.

#### **TIPS AND COMMON ERRORS**

- Choose the right patient for best results. These systems are designed only to tighten skin, so muscle laxity and excessive fat will not improve in appearance.
- Be cautious with darker skin types (types 3 to 6) in any system that uses melanin as a chromophore.

# **CONCLUSION**

As with most aesthetic procedures, patient selection is of the highest priority to maximize patient satisfaction. The aforementioned procedures work best in patients with mild to moderate skin laxity. The procedures will produce a subtle tightening of the loose or sagging skin but are not intended for correction of muscle laxity or severe skin laxity, or excess skin in overweight patients. Physicians must fully explain to patients what they should expect and what not to expect from their treatments to attain the highest patient satisfaction from any skin tightening device.

# Nonablative Radiowave Skin Tightening with the Ellman \$5 Surgitron (The Pelleve Procedure)

Michael Stampar

The demand for procedures to rejuvenate aging skin has never been greater, and the baby boomer market demands results without downtime. Nonablative monopolar radiofrequency energy (NMRFE) has been shown to contract skin in both a horizontal and vertical axis through "volumetric" heating of the dermis and subdermis. This radiofrequency (RF) energy is conducted/passed through from the dome-shaped active handpiece touching the skin, directly to a passive antenna plate placed behind the body part. Heat is generated at the dermal-subdermal junction, where fat provides the highest resistance to the flow of electrons. This increased impedance causes heating of adjacent deep dermal type one and three collagen fibrils and causes contraction of skin in a horizontal plane. Further deeper heating, with conduction through vertical connective tissue bands, running through fat from the deep dermis to the underlying fascia, has been shown to be the mechanism responsible for vertical contraction, or a "shrink-wrap" effect with NMRFE. Many different RF devices have become available, but primary care providers interested in providing antiaging procedures require technology that offers reliable results, with little to no risk of true complications, at a reasonable cost, and with a predictable range of efficacy.

The Ellman Dual Frequency S5 Surgitron device (Fig. 52-1) is unique because of the very high frequency (4 MHz, or 4 million cycles per second) it produces as compared with other RF devices. Earlier monopolar versions have been available for over 20 years as a source of RF energy for office surgery, with diverse applications in many specialties (see Chapter 30, Radiofrequency Surgery [Modern Electrosurgery]). More recently, dome-shaped, hand-held, alloy electrode treatment tips have been developed. They are to be used only with the S5 Surgitron device, to allow continuous, gradual, volumetric dermal and subdermal heating. These smooth-edged domes use low energy levels and allow constant visual, tactile, and patient-generated feedback to ensure safety.

The efficacy of thermally induced skin contraction appears to be temperature dependant and based on the number of repeat passes required to induce collagen denaturation and restructuring in any given patient. This gradually progressive heat-generating technique allows thermal injury to occur in both deep and more superficial levels of the dermis. Controlled thermal injury causes three-dimensional skin contraction with immediate as well as delayed improvement in wrinkles, texture, and pore size. Horizontal dermal contraction provides lift and tightening, whereas vertical contraction firms the skin by making the subdermal fat layer more compact. Patients seeking dermal fillers have had enough dermal thinning to

allow collapse and creasing. Volume replacement is aided by firming the subdermal "compartment" where the volumizing products are deposited. By treating not only to the point of visible contraction, but to an end point of no further observable contraction, a demonstrable result can be achieved in almost every case in a single treatment session.

The degree of improvement depends on the "skin age" more than chronologic age. The more reversibly bound collagen fibrils remaining the better, and more rapid, the immediate result. When properly used, the dome-shaped handpieces allow the physician to deliver each patient's therapeutic dose painlessly, without significant safety concerns. Favorable results have been seen in patients ranging from a 19-year-old fashion model with early fine forehead lines, to an 81-year-old with coarse neck creases. Skin in other areas of the body also has responded when heated thoroughly. The safety, reliability, and low treatment cost make skin tightening with the Ellman Dual Frequency unit (Ellman International, Inc., Oceanside, NY) a reasonable treatment modality for the primary care physician providing antiaging services. At this time, the Pelleve procedure has received FDA clearance for the treatment of moderate-to-fine facial wrinkles and folds in types I to IV skin. Neck and body use mentioned in this chapter represent "off-label" use, as does treating types V and VI skin in the United States. There are no such restrictions outside the United States.

# **ANATOMY**

The pertinent anatomy for skin tightening includes the location of the collagen bundles and vertical fibrous connective tissue bands. The greatest densities of bundles of collagen fibrils are in the deep dermis just superficial to the dermal-subdermal junction, but they are present throughout the dermis. The decrease in density of these bundles with photodamage and aging leads to dermal softening, allowing lines and creases to form. Thermal denaturation of collagen occurs at a temperature of 65° C, which causes a breakdown of covalent bonds and restructured contraction of the helical fibrils; cooling appears to cause more rapid skin contraction. The inflammatory response and subsequent repair of the thermal injury bring fibroblasts that lay down new collagen, further improving the appearance of the skin by reversing, to some degree, the aging process of the skin. The more superficially the dermis is injured by vertical penetration of the accumulating heat energy, the greater the effect on fine lines and texture.

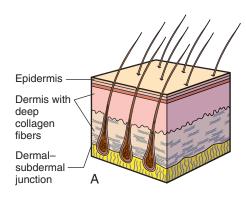

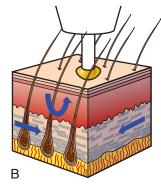

**Figure 52-1** The Ellman Dual Frequency electrosurgical unit used for the Pelleve skin tightening procedure.

The vertical fibrous septa provide the path of least resistance for further energy flow to the passive electrode. The energy flows down these bands to their fascial origin, resulting in vertical contraction of the fibrous septa surrounding fat compartments that remain cool (Fig. 52-2).

#### **INDICATIONS**

Radiofrequency-generated thermal skin tightening with the Pelleve procedure is indicated in anyone showing signs of photodamaged or aging skin. Skin laxity—ranging from early softening of contours causing a vague, tired appearance to overt sagging—can benefit from the restoration of dermal collagen integrity. Ptotic brows and

**Figure 52-2 A,** Diagram of actinically damaged or aged skin. **B,** Application of the S5 Surgitron probe. *Straight arrows* show horizontal saturation of deep collagen. *Curved arrow* shows heat rising more superficially to affect wrinkles.

jawline, double chins, and an overall "melting" appearance of the skin on the face can be improved.

Significant improvement has been seen in these areas:

- Softened jaw contours (jowling)
- Flattened brow arch with or without forehead creasing
- Nasolabial and melolabial folds
- Crow's feet
- Excess upper lid skin
- Forehead and glabellar creasing and softening
- Double chin
- Neck softening and creasing
- Perioral lip lines
- Large pores and thick skin on the nose and chin
- Aged loose skin in the face, neck, arms, and abdomen (off-label)
- Dermal-filler patients (off-label)

# CONTRAINDICATIONS AND RELATIVE CONTRAINDICATIONS

Currently in the United States the Pelleve procedure is cleared for use in patients with types I to IV skin. Despite the general acceptance that RF energy is "color blind," no patients with type V or VI skin were included in the study population. When combining RF skin tightening with botulinum toxin (Botox) or fillers, tighten first, then inject. Successful skin tightening will alter the amount of filler needed in glabellar and perioral lines and folds, so filling after skin tightening is advised. On the other hand, studies have shown no detrimental effects of heating with RF energy over all commonly used dermal fillers. Avoid heating over areas injected with Botox within 7 days to allow proper tissue penetration.

Contraindications include the following:

- The presence of any topical, local, regional, or general anesthetic that can alter the patient's perception of heat on the skin.
   Patients need to provide feedback on heat sensation to avoid burns and overheating.
- Pacemakers and implanted defibrillators (the "shielding" built into new devices decreases the risk, but patients should be cleared by a cardiologist familiar with the specific device before proceeding).
- Open skin lesions in the treatment area.
- Any neuropathy that alters pain sensation to the areas being treated.

**NOTE:** The use of anticoagulation is not a contraindication.

# **EQUIPMENT AND SUPPLIES**

- Ellman Dual Frequency 4.0 radiofrequency generator with antenna plate (other, lower-frequency units, and coagulation- or hyfrecation-only units will not work safely!)
- Dome-shaped skin tightening handpieces: 5 mm for eyelids, 10 mm for face, 15 mm for face and neck (off-label)
- Pelleve cooling gel (ultrasound gels also work well, but others may coagulate or allow burns)
- Reusable soft gel cool packs
- Eye shields for direct eyelid treatment and anesthetic ophthalmic drops
- Nonsterile 4 × 4 gauze pads
- Elastic headband

**NOTE:** Do not use any topical anesthetic on the skin!

#### PREPROCEDURE CARE

- Ask patients to arrive with no makeup or remove makeup on arrival.
- Tell patients not to take pain medications or sedatives and avoid anti-inflammatory medicines for 1 week before and 4 weeks after

the procedure, if possible, to avoid blunting the inflammatory response to the treatment.

#### **PROCEDURE**

Photos are vital and should be taken. Take them with the patient standing in five positions and with appropriately lit close-ups of wrinkles in the forehead, periorbital, cheek, or lip areas. The lighting, positioning, and framing should be standardized for your camera and facility to ensure reliable comparisons of before and after photographs. Asymmetry between the two sides of the face or brow position, orbital height, or cheek volume should be reviewed with the patient in the mirror before starting the procedure. A headband can be used to keep dispersion gel out of the patient's hair, and also adds consistency to photographs.

The Pelleve procedure is performed with the patient placed in the supine position on a treatment table that allows the operator to sit at the head. Adequate lighting should be provided to allow close observation of changes in skin redness and texture as the treatment progresses. The passive electrode pad is placed against the skin of the upper back for face and neck treatments or, when treating other areas, directly under the treatment area. The pure cut waveform is used for the most efficient delivery of the RF energy. For facial applications, the 10-mm tip is used. When treating on or around the eyelids, eye shields provided with the device should be carefully inserted after topical anesthetic drops are instilled (see Chapter 10, Topical Anesthesia). Dispertion gel can be applied directly to the skin, or the dome-shaped electrode can be dipped into a reservoir of the gel, and is spread with the continuous random circular or linear movement of the tip on the treatment area. Failure to cover all areas with a layer of gel can result in rapid excessive heat delivery and burns. The dispertion gel provides smooth gliding over the skin and keeps the epidermis cooler than the dermis, where the therapeutic heating occurs. To provide the treatment safely and painlessly, contact of the treatment electrode with the skin through the dispertion gel must be established before activating the electrode.

Prior to activating the electrode on facial skin, "patient tuning" can be done on the back of the hand to determine the approximate heat threshold for each patient. Because of variability in local and total body impedance between patients, all treatments should be started with continuous movement at a power level of 20 watts on pure cutting mode and increased a few watts at a time to find an effective but comfortable working level. Comfortable treatment levels will vary over the face and neck, with lower levels on the thinner skin of the forehead and periorbital area and higher levels in the cheek and neck areas.

The power setting should be adjusted based on patient feedback to allow a gradual, progressive warming from a "3 to 4" to a "7 to 8" on a scale where "10" would cause the patient to pull away. To optimize treatment time and patient comfort, a proper level of energy will require 10 to 15 seconds of continuous random-pattern contact to reach the heat perception level of 7 to 8 over an *area* of 6 to 10 cm<sup>2</sup>.

Treatment level and heat perception can be adjusted by changing the power level of the pure cut mode or by changing the speed of movement or amount of area covered between passes. Initially the provider may completely depend on the patient's feedback to decide when to move to the next treatment area. But, with experience, observed color and texture changes will indicate that the tissue temperature is near threshold before the patient needs to alert you to increased heat sensation. A dialogue should be maintained between the operator and patient to develop an understanding of the patient's heat tolerance and variations in heat perception in all treatment areas. Handheld infrared temperature guns can be used to spot-monitor the temperature to help avoid undertreating easily reddened skin and to monitor progress.

Slower, more concentrated movements in an area will often result in "jumping" from a 5 to 9 on the heat perception scale, whereas rapid movements over a large area may seem never to

achieve that threshold temperature to allow collagen remodeling. A compromise between these two extremes should be reached.

Passes over sensitive areas such as the orbital rim under the brow are incorporated into other periocular passes over crow's feet and the temple because all these areas require a lower treatment energy than the thicker cheek and forehead skin. Avoid heating directly over the brow hairs, as this may cause a spark gap or tattooed brows to change color.

So, in addition to patient feedback, control of the treatment level also requires observing the skin for redness, visible smoothing, and contraction. A "pass" is counted each time an area is taken from warm to almost too warm on "threshhold temperature," when visible contraction is seen or the patient repeats "that's hot." Circular or linear motions can be made (Fig. 52-3). If the patient repeatedly reports the sensation is too warm too quickly, the power setting should be turned down on the unit. Passes should be repeated until no further contraction or smoothing occurs with continued energy delivery. This end point must be reached for a demonstrable result. In general, when addressing wrinkles directly, the operator will return to the previously treated area for additional passes after going over the next one or two adjacent areas to allow some gel pack cooling between passes. When performed properly at appropriate energy settings, the procedure should be essentially painless.

In contrast to other devices that are limited by pulses to be delivered, continuous confluent energy should be applied to all facial skin, hairline to hairline laterally, and to the clavicle inferiorly when treating the neck (off-label in the United States). By extending the facial treatment to the firm, adherent skin of the scalp and over the sternocleidomastoid muscle in the neck, the contraction achieved after several passes has an anchor point for pulling the skin taut rather than simply contracting concentrically. In the midface, more energy should be delivered laterally and across the jawline, where maximal horizontal contraction and tightening will occur relative to the medial cheek fat pad areas, where vertical contraction will firm and smooth the skin. Excessive malar flattening should be avoided. All forehead and neck areas are treated evenly to the therapeutic end point of definitive visible firming, contraction, or smoothing. It will take several passes over an area to get to a point that the skin can be seen to contract, firm, or smooth with each additional application of heat, followed by a cold pack. In a splitface, one-month study of four consecutive patients, the author demonstrated greater midface contraction when heating and cooling, versus just heating, was used.

The time it takes to treat adjacent areas to tolerance allows enough cooling time to then *return to the initial area for added passes*. If discomfort occurs immediately, decrease the energy level or terminate the treatment for that area. The skin will progress to a point of no further contraction in two to five additional passes after seeing contraction after the first pass. Typically, one pass in each area per decade of age is required for maximal contraction and smoothing.

A full face and neck procedure takes approximately 40 to 60 minutes, depending on the skin condition and size of the patient.

At the point of completion for an anatomic area, *cold gel packs* are applied with gentle pressure in the desired direction of contraction to rapidly chill the freshly denatured collagen bundles, primarily in the midface, where three-dimensional contraction provides lift. The theory behind this is that rapid cooling will force tighter contraction of covalent bonding of the collagen helices, similar to setting a molten mold.

**NOTE:** Care should be taken not to activate the electrode treatment tip before skin contact is established and not to lose contact while energy is being delivered. Disrupting the contact between the treatment electrode and the dispertion gel while the electrode is active will cause a spark gap to occur, which causes an "electric shock"-type feeling. This can happen if the patient pulls away, the operator pulls away, a dry area is touched, or thicker hair is crossed. This typically startles the subject but has not been observed to cause any significant

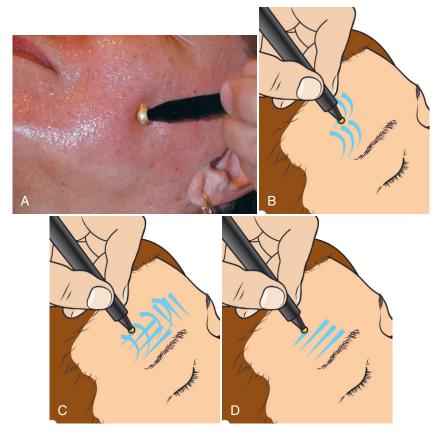

Figure 52-3 The energy is delivered using random geometric patterns such as swirls and horizontal and vertical strokes. The purpose is to deliver a confluent heating to all treated skin and to avoid any nonrandom movement that could theoretically leave a treatment pattern visible in the soft tissues. A, The Pelleve probe contacting the skin. B, Circular pattern. C, Linear and circular patterns (superimposed). D, Linear pattern.

epidermal damage. If stretching the skin is desired, hold gauze with a gloved hand on a dry area away from the actual active treatment site to avoid grounding yourself.

With this technique of treating gradually but progressively to the point of apparent maximal skin contraction, every patient should see and feel tightening, smoothing, lifting, or sculpting, depending on the aging characteristics being addressed. The degree of improvement depends on the "skin age" more than chronologic age. The more reversibly bound collagen fibrils remaining, the better, and the more rapid the immediate result. Skin in all areas can be tightened. A photograph of the half-treated face can be taken to document the treatment effects compared with the untreated side.

Figure 52-4 shows a patient before treatment and 2 months after Pelleve. In most patients, a touch-up treatment 4 to 8 weeks after the original treatment typically yields an additional 10% to 20% improvement, possibly addressing post-treatment relaxation or incomplete collagen denaturation. These "touch-ups" typically take only two to four passes and always show more rapid heating than the original treatment. The greater the laxity, the greater the response to a second or third procedure. The patient should be advised that treatment results should continue to improve for up to 4 months based on the physiology of thermal tissue injury and that they may repeat the procedure every 1 to 2 years as needed after a desired end point is reached.

### **COMPLICATIONS**

- Very limited
- · Discomfort if power is set too high

- Rarely, a burn caused by activating the electrode before making contact or after losing contact
- Possible lack of intended tightening because of inadequate residual collagen
- Inadequate effort

### **POST-TREATMENT CARE**

There should be no downtime with the Pelleve skin tightening procedure when performed properly. Transient reddening of the skin should resolve in 1 to 3 hours, and no change in skin care is required. Makeup can be applied immediately. They are also advised to take 1000 mg of vitamin C daily in oral form for 6 months to ensure an adequate systemic supply for collagen synthesis. Patients are reevaluated at 6 weeks, 6 months, and 1 year following the procedure. Additional RF treatments are recommended every 6 to 8 weeks for six months, or until the patient is satisfied a maximal result has been achieved (for patients with excessively wrinkled or lax areas). Light peels, filler injections, Botox injections, or surgery can be done any time after the treatment.

Ellman is the sole supplier of the device worldwide. The most significant observed advantages of this device and treatment relative to other RF-based devices and treatments are the tactile control of the treatment; gradual, progressive, continuous heating rather than pulsing; demonstrable results in a single, essentially painless treatment; and the cost of delivery. A bipolar treatment tip is being evaluated at this time and will be available with the same device if additional efficacy is seen.

Figure 52-4 Appearance of the skin before (A) and after (B) Pelleve treatment.

### **CODING AND BILLING**

This is an aesthetic procedure so there are no CPT/ICD-9 codes.

# Fractional Laser Skin Resurfacing

Gregory A. Buford

### HISTORY OF LASER RESURFACING

Facial aging follows a rather predictable course. As we age, our skin thins and becomes translucent, the collagen fibers in the deep dermis diminish in number and become more randomly organized, and pigmentary changes appear in more superficial layers as a result of years of actinic damage. Some of these changes can be ameliorated or reversed. To do so, the skin must be injured in a predictable manner that stimulates it to reorganize and rejuvenate during the healing process. Chemical peels, microdermabrasion, and laser rejuvenation have been used successfully in the past, but each has its own inherent advantages and disadvantages. In this chapter we focus on laser resurfacing and, most important, *fractional* laser resurfacing.

Lasers were developed in 1960 on the foundation of Einstein's quantum theory of radiation. Over time, the use of different lasing media allowed for the development of specific lasers and ultimately specific applications. Ablative laser resurfacing was first introduced in the 1990s with the advent of the CO<sub>2</sub> laser; soon thereafter, the erbium-doped yttrium aluminum garnet (Er:YAG) laser was released.

Although these two lasers formed the foundation of ablative resurfacing, they provided slightly different outcomes with respect to treatment efficacy, downtime, and risk for adverse events. The shorter wavelength of the erbium laser (2940 nm) versus the  $CO_2$  laser (10,600 nm) allowed for more effective absorption of laser energy by water and thus a significantly higher absorption coefficient (Er = 12,000 vs.  $CO_2$  = 800). As such, residual thermal damage was significantly less with use of the erbium laser than with the  $CO_2$  laser. In addition, faster reepithelialization was noted with the erbium laser. But were these advantages necessarily decisive? Perhaps not: although the erbium laser has been associated with less downtime and erythema and a faster recovery, its overall results have been less dramatic than those attained with use of the  $CO_2$  laser.

In response to the prolonged downtime associated with traditional ablative resurfacing, which is quite aggressive, a number of nonablative technologies were developed with the aim to provide noninvasive facial rejuvenation but to do so with minimal to no downtime. Technologies such as intense pulsed light (IPL), radiofrequency lasers, and infrared lasers were ultimately developed. While the downtime with these devices was definitely less, the overall results also were less impressive.

The next evolution of laser technology involved reintroduction of the erbium laser but in a "fractional pattern," with the first device to pioneer this technology being the Fraxel Laser (Solta Medical, Inc., Hayward, Calif). Fractionated resurfacing uses many small, separate columns of light to create microthermal treatment zones (MTZs) with bridges of untreated tissue in between. In the case of the Lumenis (Santa Clara, Calif) Ultrapulse Encore, spot size varies from 0.12 mm (DeepFX) to 1.3 mm (ActiveFX) and can be applied in a square, rectangular, linear, or other shaped configuration. The

treated area appears as many small ablated "dots" as opposed to a single large, homogeneous ablated area. By leaving areas untouched, treated areas heal faster because of ingrowth from the surrounding untreated zones. The result is dramatic improvement with significantly less downtime.

Although fractionated erbium laser technology was a significant step ahead of its predecessors, the disadvantages were also clear. Most patients were seeing improvement, but it came at the cost of at least three to five treatment sessions. So although downtime was minimal, the overall duration of therapy was prolonged. Eventually, fractional technology was extended to a  $CO_2$  platform, which then allowed for more effective rejuvenation in as little as one treatment.

### **BASICS OF LASER THERAPY**

Ablative devices such as the  $CO_2$  and erbium laser use water as a target chromophore. As previously noted, the erbium wavelength is nearly 20 times more highly absorbed than the  $CO_2$  wavelength. This difference effectively differentiates the two lasers. The absorbed laser energy then exerts two effects on the treated tissue: ablation and coagulation. Ablation involves actual destruction and removal/vaporization of tissue and can be beneficial in improving the superficial tone, texture, and appearance of the skin. Coagulation, on the other hand, is the result of heat transference to the tissue and is thought to encourage collagen remodeling and ultimately tissue tightening.

The amount of ablation and coagulation is controlled by the amount of laser *fluence* (power) and *pulse duration* (or *pulse width*; length of time power is applied). Short pulse durations and high fluence produce greater ablation, whereas longer pulse widths and lower fluencies emphasize coagulation. Settings can therefore be individualized for the desired patient outcome.

The percentage of skin treated is dictated by the *density* setting. Higher density settings affect a greater area within a specific treatment zone (i.e., the columns of light energy are closer together) and can be especially effective for dyschromias. The downside is that there may be a prolonged healing time, depending on the chosen fluence, because there are fewer untreated skin islands surrounding treated areas.

Although there are basic recommendations for treatment parameters for each device, in reality there is considerable variation among practitioners (Table 53-1). In the beginning stages, it is best to incorporate more conservative settings and accept the potential need for additional treatment, versus using more aggressive settings with the greater potential for complications.

### **PATIENT SELECTION**

Patient education and selection are essential for achieving optimal results with fractional laser resurfacing. Fitzpatrick skin type

	actional Technol					
Supplier Product Name	Device Type	Wavelength	Energy Output	Pulse Length	Price	Accessories
<b>Alma Lasers</b> Pixel 2940	Fractional Er:YAG handpiece for Harmony <sup>XL</sup> system	2940 nm	2500 mJ/p	N/A	Contact mfr.	Pixel 2940 handpiece.
Pixel CO <sub>2</sub>	Fractional CO <sub>2</sub> system	10,600 nm	30 W	N/A	\$69,900	7 × 7 and 9 × 9 pixel array handpieces, two surgical handpieces.
Pixel Omnifit	Pixelized handpiece for existing CO <sub>2</sub> systems	10,600 nm	N/A	N/A	\$34,900	7 × 7 and 9 × 9 pixel array configuration.
<b>Cutera, Inc.</b> Pearl Fractional	Fractional 2790 nm YSGG	2790 nm	60–320 mJ per microspot	600 msec	Contact mfr.	Smoke evacuator connector.
<b>Cynosure</b> Affirm CO <sub>2</sub>	CO <sub>2</sub> with scanner	10,600 nm	30 W	0.2–20 msec ablative, 0.2–2 msec microablative	Contact mfr.	Scanner (microablative and full ablative).
<b>Eclipse, Ltd.</b> SmartXide Dot	CO <sub>2</sub> laser and scanner system	10,600 nm	30 W	0.2–80 msec	Contact Eclipse	Scanner offers standard or dot scanning mode.
<b>Ellipse, A/S</b> Juvia	Fractional CO <sub>2</sub> laser	10,600 nm	0.1-15 W	N/A	Contact mfr.	Truly flexible fiber delivery. Built-in parameter controls on handpiece. Adjustable scan dwell times: 2 msec, 3 msec, 4 msec, 5 msec, 6 msec, 7 msec. Scan density: $7 \times 7$ ; $9 \times 9$ ; $11 \times 11$ MTZ/cm². Scan area: 1 cm²; MTZ (spot) size: 500 $\mu$ m. classification is a basic way to identify patients at higher risk for pigmentary changes associated with laser resurfacing (see Chapter 46, Introduction to Aesthetic Medicine). Lighter-skinned patients (Fitzpatrick types I to III) are at lowest risk for postprocedure pigmentary changes, whereas darker-skinned patients (Fitzpatrick types IV and V) are at a much higher risk. Although darker-skinned patients can still be treated, more conservative settings must be chosen and they must be carefully counseled about the specific risks they may encounter.

The most important area of patient education, however, is in identification of expectations. Although laser resurfacing can achieve some degree of skin tightening and improve tone and texture, it is no replacement for surgical intervention in the patient who really needs a facelift or necklift. Sagging skin and jowling are surgical problems and cannot effectively be addressed with laser resurfacing alone. Using various combinations of procedures, however, these patients can often achieve synergistic results that go far beyond either intervention (surgical or nonsurgical) alone. In addition, realistic healing and recovery time must be discussed with the patient, as well as the need for patience while waiting for final results, which may take 4 to 6 months. Proper patient selection before treatment is essential for achieving optimal results and can generally allow one to avoid many of the pitfalls associated with unrealistic expectations.

### **INDICATIONS**

- Laser resurfacing can be an effective means for treating the following age-related conditions:
  - Dyschromias (pigment changes): Areas of hyperpigmentation can effectively be addressed with fractional resurfacing. Because only light treatment settings are required, the downtime is often as short as 2 to 3 days (Fig. 53-1).
  - Textural changes: As aged skin is replaced with new tissue, there is diminishment in the wrinkled, crepey appearance because the collagen matrix is stimulated to regenerate and reorganize (Figs. 53-2 and 53-3).
  - Fine lines and wrinkles: Improvement in fine lines and wrinkles has been noted after laser resurfacing, but improvement is known to be enhanced after pretreatment with botulinum toxin type A. With movement stabilized in the treated areas, the newly regenerated skin is allowed to heal in a more stable environment (Fig. 53-4).
  - Dilated pores: Many patients notice refinement of pore size, although this effect may take upward of 6 months to fully achieve
- Scars (surgical vs. traumatic vs. acne vs. burns): By effectively
  planing down the scar and stimulating collagen remodeling,
  fractional resurfacing can have a beneficial effect on the

Figure 53-1 Treatment of dyschromias using a Lumenis Ultrapulse Encore Laser. ActiveFX: 100 mJ, 600 Hz, density 100%, single pass; DeepFX: 12.5 mJ, 300 Hz, density 15%, single pass. A, Before treatment. B, Three months after treatment. (Courtesy of Gregory A. Buford, MD, FACS, Denver, Colo.)

appearance of scars from a variety of sources (Figs. 53-5 through 53-9).

 Stretch marks (questionable efficacy): Although results are variable, some practitioners report improvement in the appearance of stretch marks; however, there are very few well-controlled studies in this area.

### **CONTRAINDICATIONS**

### **Absolute**

- Keloid formers
- Bacterial or viral skin infection
- Use of isotretinoin in the past 12 months

- Scleroderma
- Prior radiation therapy to area
- Localized poor healing
- Melanoma or identified lesions suspect for skin cancer in area to be treated
- Ectropion
- Vitiligo
- History of noncompliance with previous treatments

### Relative

- Impaired immune system or known autoimmune disease
- Collagen vascular disorder
- Lower lid laxity

- Photosensitizing medications
- Fitzpatrick skin type IV or V

### PRETREATMENT PATIENT EVALUATION

- Skin type classification: Fitzpatrick skin type classification should be determined before treating any patient with fractional or nonfractional laser resurfacing (see Chapter 46, Introduction to Aesthetic Medicine). Darker skin types are at a higher risk for long-term pigmentary changes even with fractional technology, so the degree and number of treatments should be adjusted accordingly.
- Current medications: Any medications that will delay or impede wound healing should be discontinued before laser resurfacing.
- Previous treatment with lasers or deep chemical peels: Prior treatment
  with either deep chemical peels or lasers in the same area should
  be considered before retreatment, given the potential for delayed
  or impaired healing.
- Desired end result: One of the most critical variables in success is patient expectation, so it is important to have an open and honest discussion with each patient before moving forward with any aesthetic procedure. Managing expectations before treatment will better prepare your patient for outcome in both the short and long term. Speak candidly and honestly about the following:
  - Number of treatments
  - Anticipated costs
  - Recovery time
  - Degree of discomfort
- Pretreatment/post-treatment protocol (e.g., skin care products, patient instructions): The outcome of any aesthetic procedure is often the result not only of the success of the procedure itself but of the patient's compliance with recommended protocol instruc-

- tions before and after the treatment. This is especially true with laser resurfacing. Although some experts dispute the importance of an individualized and guided medical skin care regimen before the laser procedure, most agree that it is essential during the healing period.
- Adjunctive treatment with botulinum toxin type A: As demonstrated by multiple authors, treatment with botulinum toxin type A allows for more optimal and potentially sustained results when undertaken before laser resurfacing. As one study supports, the practice effectively prevents dynamic facial muscular action in treated areas and potentially minimizes the reestablishment of expressive wrinkles and folds.
- Discussion of risks/benefits and informed consent: As with any procedure, informed consent must be obtained after discussion with the patient of associated risks and benefits. Be realistic in describing downtime and discomfort, with the understanding that there is a degree of variation depending on individual patient characteristics, treatment settings, and the specific device used.
- Pretreatment photographs: The importance of pretreatment photographs cannot be overemphasized. Aside from the ability to document degree of improvement from the pretreatment to post-treatment stages, taking photographs of your patients also provides you a means with which to educate other patients on the efficacy of these procedures.

### **BEFORE THE PROCEDURE**

The laser treatment itself must be performed by a trained laser professional under medical supervision. State laws dictate the actual degree of medical supervision and who can actually perform the procedure.

*Pain control* should be addressed and individualized, and is really a factor of four variables.

- 1. Patient pain tolerance
- 2. Specific device
- 3. Depth of treatment
- 4. Area of treatment

With other rejuvenative procedures, some patients require very little analgesia, whereas others have less tolerant pain thresholds. The key is to understand the average patient's needs, begin there, and then fine-tune accordingly. It is always better to make your patients more comfortable than less because their experience will largely be shaped not only by the outcome they eventually receive but by the initial experience they perceive.

A variety of methods can be used to manage pain in an office setting:

- Topical anesthesia: For all fractional laser treatments, this is the foundation of pain management and may include a wide variety of topical agents. A frequently used compounded combination is a 23% lidocaine/7% tetracaine cream, which is applied 45 to 60 minutes before treatment. As with any treatment, check for potential allergic reactions before proceeding and watch for signs and symptoms of toxicity. Although with facial resurfacing there is less risk than with extended treatment areas (e.g., laser hair removal), the risk is not zero and so all patients must be observed for evidence of impending toxicity and a resuscitation plan must be in place before any treatment is begun.
- Nerve blocks (see Chapter 8, Peripheral Nerve Blocks and Field Blocks, and Chapter 9, Oral and Facial Anesthesia): For more aggressive treatments around the mouth, infraorbital and mental nerve blocks can be used. One milliliter of 2% lidocaine with epinephrine per injection is extremely effective in achieving an acceptable degree of patient comfort. However, warn the patient when transitioning from a blocked to a nonblocked area. Pain control can be so effective using blocks that it can make the transition to an area where only a topical anesthetic was used significantly more sensitive.
- Oral medications: Although many practitioners combine some type of either narcotic or non-narcotic (e.g., nonsteroidal antiinflammatory drugs [NSAIDs]) pain medication with an anxiolytic for their pain management program, it does more to manage acute anxiety than pain. As such, a light anxiolytic (diazepam) may be best so that the patient is still aware of her or his surroundings but, at the same time, lightly relaxed.

# PREPARING FOR THE TREATMENT (AT LEAST I WEEK PRIOR)

- Discuss and obtain informed consent from the patient (see sample consent form online at www.expertconsult.com).
- Review all written postprocedure wound care instructions with the patient and encourage her or him to call the office for any concerns or suspicion of poor healing associated with the treatment.
- Take pretreatment photographs.
- Schedule postprocedure appointments.
- Make sure that the patient has the necessary skin care products for the immediate postprocedure healing period.
- Give the patient Swiss Therapy Eye Masks (if performing periorbital rejuvenation).
- Give the patient prescriptions for all medications related to the treatment and encourage him or her to fill these before the day of the procedure:
  - Antiviral (regardless of prior history of herpes simplex)
  - Ophthalmic antibacterial ointment (if performing periorbital rejuvenation)
  - Anxiolytic or analgesic
- Patients should discontinue the use of aspirin, NSAIDs, vitamin E, St. John's wort, and other dietary supplements, including

- ginkgo biloba, evening primrose oil, garlic, feverfew, and ginseng, at least 2 weeks before treatment to reduce the risk of bleeding.
- Remind the patient to bring sun-protective clothing (e.g., widebrimmed hat and sunglasses) on the day of the procedure.
- Arrange for a driver for the day of the procedure (regardless of whether the patient will be medicated for the actual treatment).

### **SUPPLIES**

### **Before**

- Topical anesthetic (to be applied 45 to 60 minutes before the procedure)
- Metal eye shields (intraocular vs. extraocular) plus ophthalmic ointment and anesthetic drops
- Protective laser goggles for all present during the treatment
- Smoke evacuator
- Gloves
- Surgical mask
- 4 × 4 gauze sponges (for wiping away fluid from treated areas and from periorbital area)
- Moistened towels (to be placed below the neck to protect the chest)
- Zimmer Chiller (or other cooling device)
- Laser

### After

- 4 × 4 gauze sponges
- Ice water
- Bowl
- Hand towels\*
- Aquaphor
- Swiss Therapy Eye Masks

### SKIN PREPARATION

Before the actual procedure, the skin must be prepared in the following steps:

- 1. All makeup removed
- 2. Skin cleansed with mild cleanser
- 3. Numbing eye drops placed (when using intraocular eye shields)

### **TREATMENT**

- The patient should arrive 45 to 60 minutes before the procedure. At that time, all makeup is removed, the skin is cleansed with a mild cleanser, and topical anesthetic is applied to treatment areas. The anesthetic is left in place a minimum of 45 minutes.
- Immediately before the procedure, topical anesthetic cream is removed and the skin is again cleansed with a mild cleanser.
- Position the patient so that both the clinician and patient are comfortable. Whereas some prefer to treat in a flat, supine position, others find it easier to elevate the head of the bed to approximately 30 degrees and treat from the standing position.
- If using eye shields, instill one or two drops of ophthalmic anesthetic solution into each eye. Lubricate the shield side facing the cornea with an appropriate ophthalmic ointment. If the patient is wearing contact lenses, remove them. Gently place the corneal eye shields onto the patient's eyes.
- Make sure that all staff members present have the appropriate laser-protective eyewear.

<sup>\*</sup>Before the procedure, the towels are placed in the ice-water slurry to chill. After treatment, the chilled towels are applied to treated areas and left in place for at least 10 minutes. The skin is then gently dried and a thick coating of Aquaphor is applied.

(1.3-mm Spot Size)

 Next, consider the following variables when deciding on specific treatment settings:

80-100

50-60

- Specific treatment area
- Desired depth of treatment
- Desired effect of treatment
- Specific skin type

Neck, décolleté

Hands, forearms

- Choose the appropriate settings (i.e., fluence, density, pulse width, shape, repeat time) for the patient and select them for the device. Each particular laser has certain parameters recommended by the company. It will be important to receive training for the unit purchased. Begin with the suggested parameters and adjust them as needed only after gaining experience (Tables 53-2 through 53-4).
- Perform a test spot on a tongue depressor to ensure that the laser is functioning correctly and that you have chosen appropriate treatment settings.
- Begin treatment, observe reactions of the skin to the laser energy, and make any appropriate adjustments. Most practitioners will treat a specific zone as a whole and then move onto the next zone. This provides for a more coordinated approach and allows for differential treatment settings for each individual zone.
- Inform the patient when you are moving onto a different treatment area and be cognizant of her or his pain tolerance. Application of the laser feels like a rubber band snap and can be startling to the patient if the area being treated suddenly shifts from the chin to the upper forehead. Remember, pain tolerance is highly subjective and some patients will need to have their treatment settings adjusted accordingly.
- After standard treatment has been concluded, dial down the settings and "feather" along the jawline and hairline. Feathering blends the treated and untreated areas so there will not be a fine demarcation line between the two when healing is complete. It can be done in several ways: turning the treatment probe at an angle so the penetration is not so deep, or moving the handpiece faster to spread out the density of the columns.
- When treatment is complete, immediately remove the eye shields or protective eyewear and apply cool, damp towels to all treated areas. The towels should remain in place for at least 10 minutes to allow for egress of any residual heat.
- The skin is then dried and an occlusive dressing or ointment applied. This is extremely important, and the patient must under-

stand the importance of keeping the treated tissues moist for the next several days.

On

On

The patient is then discharged and asked to call in the morning for a status report, or earlier if having problems. Encourage plenty of fluids to stay well hydrated because patients tend to lose a significant amount of fluid from their skin during the early healing process. Also suggest avoidance of high-sodium meals because increased salt intake will merely add to the normal and anticipated degree of postprocedure swelling.

### **Details of an Actual Patient Treatment**

0.3-1.5

0.3-1.5

The patient is a 65-year-old white woman with advanced facial aging and significant facial laxity. Although she would have benefited from an aggressive ablative CO<sub>2</sub> laser resurfacing, she did not want the associated downtime. The Lumenis Ultrapulse Encore fractionated CO<sub>2</sub> laser treatment was recommended. She underwent this initial treatment in the office with topical anesthetic cream alone and was very comfortable.

Key areas during her treatment session and a few pearls are as follows:

- The patient is a middle-aged white woman with advanced facial aging (a combination of coarse and fine rhytids, facial laxity, and scattered dyschromias; Fig. 53-10A).
- After 45 minutes of topical anesthetic cream use, her skin is degreased, cleansed, and dried. Instill topical anesthetic drops into her eyes and then place lubricated metal eye shields to provide corneal protection during treatment. Once settings have been chosen, test them on a tongue depressor before actual treatment (Fig. 53-10B).
- While the patient is in a semiupright position, treat the forehead first (Fig. 53-10C and D). This area generally requires moderate treatment settings, and this patient was pretreated 2 weeks earlier with botulinum toxin type A to the upper one third of the face to ensure a relaxed post-treatment healing environment.
- Figure 53-10C and D show the application of outward-directed tension to the treated skin to achieve more even penetration of the laser to this area. The pattern is overlapped by around 10% to 20% on the borders. Figure 53-10E shows detail of the fractional pattern, which leaves intact interspersed skin bridges.

TABLE 53-3 Recommended Treatment Settings for Lumenis Ultrapulse Encore Laser DeepFX (0.12-mm Spot Size)

Treatment	Energy (mJ)	Scan Size (mm)	Density	Hertz	Repeat Delay (sec)	No. of pulses	No. of Passes

<sup>\*</sup>Settings depend on thickness of scar tissue and body area treated. Courtesy of Lumenis, Inc., Santa Clara, Calif.

- Figure 53-10E also shows treatment of the lower perioral subunit and emphasizes the overlap of treatment zones (this provides for more even treatment).
- Figure 53-10F shows application of a second pass. The skin is stretched in this area because the patient has a moderate degree of laxity and, if not stretched, her skin would be unevenly affected. This second pass is reflected as a much darker treatment zone.
- When treating around the eyes, the upper lids are usually done
  first, followed by the lower lids. This area requires extreme
  caution. Eyelid skin is the thinnest skin on the body and so great
  care must be taken to avoid complications. Before treating this
  area, be sure to assess for lower lid laxity (to minimize the risk for
- postprocedure ectropion), and always have eye shields in place. Figure 53-10G shows the treatment lines beginning 1 to 2 mm directly above the upper lash line, followed with another row directly above. The skin is stretched to achieve even penetration.
- For the lower lids (Fig. 53-10H), use a tongue depressor to sweep
  the eyelashes superiorly to reduce the risk of singeing them. Begin
  about 1 to 2 mm below the lower lash line and then paint a line
  across the treatment area, followed by blending with the previously treated upper cheek zone. To complete the periorbital area,
  change to a smaller pattern and effectively fill in the blanks.
- Once all subunits are treated, feather all the edges (see earlier discussion) by dialing down the energy and turning the handpiece at an angle so that the beam appears elongated. Also, move the

**Figure 53-10** Actual client treatment using the Lumenis Ultrapulse Encore fractionated CO<sub>2</sub> laser. **A,** Preprocedure photograph. **B,** Testing settings on a tongue depressor before treatment. **C,** Treatment of the forehead aesthetic subunit. **D,** Completion of treatment of the forehead aesthetic subunit. **E,** Treatment of the perioral subunit with overlapping of pulses with use of the Zimmer cooling unit for intraprocedure pain relief. **F,** Treatment of the perioral subunit with two passes at the same setting to address more advanced localized aging.

- wand rather than holding it stationary. Figure 53-10I demonstrates feathering the lower jawline onto the neck.
- Figure 53-10J shows the final appearance after a single ActiveFX
  pass to the face as well as a second pass to the perioral area. The
  second pass effect around the mouth creates a slightly denser
  appearance, but was necessary given the degree of facial aging in
  this area.
- Remove the patient's eye shields and rinse the eyes with balanced salt solution. Apply cool, moist towels (that have been sitting in an ice-water slurry during the actual treatment) and leave them on for at least 15 minutes to allow heat to dissipate from the patient's skin (Fig. 53-10K).
- Reiterate the essentials of the postprocedure care regimen with both the patient and whoever is accompanying her for discharge. There will be an early striping effect (which is natural) and a mild to moderate degree of swelling (Fig. 53-10L). Emphasize that the swelling will be pronounced for the next 3 days but that it will resolve, how quickly depending on the depth of treatment.

- During that time, the patient needs to stay upright as much as possible and keep the area cool to facilitate lymphatic drainage and resolution of postprocedure edema.
- Give your office and on-call number and instruct the patient to call for any significant concerns. Complications of laser resurfacing can generally be avoided if the appropriate steps are taken early.

### **Treatment Caveats**

As with any treatment, there are a number of ways to achieve optimal results. There is significant variation among practitioners as to which variables provide the best outcome. Keep in mind that the safest treatment is generally the simplest treatment and that exotic settings, although they may prove successful in highly experienced hands, can be dangerous in the hands of someone in the beginning stages. Use the most basic settings when you start and adapt as you gain experience. Your patients are much more likely to respect an

Figure 53-10, cont. G, Treatment of the upper and lower lids. H, Treatment of the lower lid skin and use of a tongue depressor to decrease eyelash singeing. I, Feathering of the junction between treated and nontreated tissue. J, Close-up of the perioral treatment area to illustrate appearance of a double pass. K, Placement of moist, cool towels to the face immediately after treatment. L, Patient appearance after treatment and 15 minutes of cooling. (Courtesy of Gregory A. Buford, MD, FACS, Denver, Colo.)

approach where they may need to come back for a second treatment rather than an overly aggressive approach where they may be at risk for adverse events.

There are a number of controversies in the medical field as to which settings are most important and which should be emphasized when addressing specific needs or end points. With that said, the following are a few suggestions, but they are by no means the only ways to achieve optimal results:

- Pulse coverage: Position the coverage area for each pulse so that treatment zones are adjacent with very little (maximum of 10%) to no gapping between them.
- Density: Use a density setting right in the middle when treating
  photoaged skin. For the patient with dyschromias, dial down the
  fluence and dial up the density so that there is a more focused
  treatment directly over the affected area. For generalized dyschromias, treat the entire area this way; for a localized area of pigmentation, focus simply on the specific area.
- Fluence: There is a tremendous amount of controversy as to the
  optimal fluence. Look at the patient to decide. For a patient with
  mild photoaging, use a light setting; for an older patient with
  more advanced photoaging, dial up the setting. However, be very
  careful in the older patient, whose thinner skin may not tolerate
  a higher setting, leading to delayed healing.
- Pulse stacking: Avoid this until comfort is gained with a specific device. Pulse stacking takes a particular fluence and associated depth of penetration and drives it even deeper. Although there are many advocates of a low fluence doubly stacked, there is still significant controversy as to whether this is more effective than simply increasing the fluence in the first place. There is also the issue of heat dissipation. Keep in mind that double stacking may not allow for adequate heat dissipation, so there may be more of a coagulative effect. That can be good and bad, as discussed

- earlier. I would strongly discourage you from incorporating this technique until you have considerable experience with your specific laser because the results can often be unpredictable even in the hands of a highly experienced practitioner.
- Hertz rate: This is another controversial area. When treating scars, a higher hertz rate may be necessary. However, the science behind this approach is still being actively investigated.
- Treatment of erythema: More and more patients want less and less downtime but ultimately the same results. The problem, however, is that the treatment injures the tissue and the tissue needs to fully heal to achieve optimal results. It is best not reduce the erythema for at least 4 to 6 weeks because this enhanced vascularity is part of the overall healing process. Encourage the patient to be patient, and if the erythema is reasonable, wait for at least 4 weeks before intervening with either steroids or intense pulsed light.
- Combination therapy: There are a number of excellent reports documenting enhanced long-term results using pretreatment with botulinum toxin type A 1 to 2 weeks before the actual laser treatment. In addition, deep placement of volumizing fillers in conjunction with laser rejuvenation can also provide for a more comprehensive result because laser therapy will do nothing to replace lost volume (Figs. 53-11 through 53-13).
- Treatment of nonfacial areas: Extension of laser resurfacing to the neck, chest, and hands allows blending of treated with nontreated areas but it is also carries an increased risk for adverse events. These areas lack the abundant adnexal glands present in the face and so tend to heal less effectively. In addition, tissue of the chest and hands tends to be much thinner with very little underlying subcutaneous tissue. The close proximity of bone to the skin can create a heat sink and actually prevent effective heat dissipation. Aggressive treatment in these areas can lead to delayed healing and worse. Be conservative. Educate your patients about the

differences in these areas and tell them that it may take several treatments instead of the single treatment that was effective for their face (Fig. 53-14).

### POSTPROCEDURE PATIENT CARE AND INSTRUCTIONS

There are a number of ways to optimize results after laser treatment. The following home care guidelines are one example.

### **Immediately after Treatment**

- 1. Make a 1-week follow-up appointment.
- 2. Avoid direct sunlight to the face, even when just driving home from the office.
- 3. When in the car, turn on the air conditioner or roll down a window to aim cool air at the treated area.
- Place a piece of gauze between the bridge of the nose and eyeglasses to avoid irritation to the treated skin if that area was treated.

Figure 53-13 Combination therapy using a Lumenis Ultrapulse Encore Laser. *Periorbital area*: ActiveFX: 80 mJ, 125 Hz, density 82%, single pass; DeepFx: 12.5 mJ, 300 Hz, density 15%, single pass. *Perioral area*: ActiveFX: 125 mJ, 125 Hz, density 100%, single pass; DeepFx: 22.5 mJ, 300 Hz, density 20%, single pass. *Remainder of face*: ActiveFX: 125 mJ, 125 Hz, density 82%, single pass; DeepFx: 17.5 mJ, 300 Hz, density 15%, single pass. *Pretreatment with poly-Llactic acid*: medial and lateral cheeks. *Pretreatment with botulinum toxin type* A: forehead, glabella, lateral brow, and crow's feet. **A,** Before treatment. **B,** After treatment. ### First 2 to 4 Hours after Treatment

- 1. Take an analgesic (acetaminophen or ibuprofen) for discomfort.
- You will be sent home with a container of Thermal Spring Water. Spray this on your skin as often as needed to cool the skin.
- 3. Avoid direct application of ice to skin. Apply cooling vinegar compresses with cold, wet washcloths using 1 tablespoon of white vinegar in 1 cup of cold water. This will help draw out heat.
- 4. Blow air from a fan to help with the cooling process.
- 5. When intense heat subsides, apply Aquaphor Moisturizer, avoiding the area close to the eyes. Keep treated areas covered (thickly) with Aquaphor Moisturizer up to 3 to 4 days, depending on depth of treatment. The skin must not dry out! For the area around the eyes, apply the ophthalmic ointment prescribed and cover with a Swiss Therapy Eye Mask. These will tend to warm and dry out in about 20 to 30 minutes, so always keep an extra one in an ice-water bath and change as necessary.

### First Night

- 1. Sleep on your back and with your head slightly elevated (continue every night until swelling subsides).
  - **TIP:** Place a towel over your pillow to protect it from the Aquaphor Moisturizer.
- 2. Avoid environmental irritants (e.g., dust, dirt, sun, hairspray) during the healing process.

### Day I (First Day after Treatment)

- 1. Stay indoors and avoid direct sunlight.
- Begin washing treated areas two to three times a day by gently removing Aquaphor Moisturizer with the vinegar/water combination, then cleansing with gentle cleanser and tepid water. Do not rub the skin—gently pat it! Tepid showers and washing the hair is permitted.
  - TIP: Stand with your back to the shower.
- Generously (thickly) reapply occlusive ointment to all treated areas.
- Hydrate and eat healthy foods. Avoid alcohol because it will tend to dehydrate you. Also avoid exercising until the areas are completely healed.

### Day 2

1. Continue to wash the face two to three times a day with gentle cleanser and tepid water.

- Itching (particularly along the jaw line) begins and is generally an indication that the healing process has started. Mild to moderate itching is normal; if there is severe itching, call the doctor's office.
- Clinique Medical Recovery Week Complex works well for the itching areas.
- Continue to apply extra Aquaphor ointment and cool compresses. An oral antihistamine such as diphenhydramine (Benadryl) or loratadine (Claritin) may help.
- 5. Avoid picking and scratching.

### Day 3

- Continue to wash the face up to two to three times a day with gentle cleanser and tepid water.
- Itching may persist. Use your Clinique Medical Recovery Week Complex.
- 3. The central area of the face may begin to exfoliate (peel), leaving behind soft, pink tissue.

# Days 4 to 7 (Progress Depends on Depth of Treatment)

- 1. Itching has usually subsided. If not, continue using an antihistamine, especially at bedtime.
- Exfoliation begins. Use the NIA 24 Cleansing Scrub if your skin has completely healed.
- Transition to the Clinique Medical Optimizing Treatment Cream with or without the Recovery Week Complex and spottreat drier areas with Aquaphor Moisturizer.
- 4. Start your Clinique Medical sunscreen.
- 5. Most female patients will be able to apply mineral makeup to treated areas. For male patients, solid sun protection factor is available to help camouflage temporary redness. Be sure to use a fresh applicator and cleanse it with antibacterial soap between applications.

### Day 7 and beyond

- Start your regular skin care program as long as the treated area is healed. Do not use harsh, very active, or strong acids (e.g., Prevage, Retin-A) for 1 month.
- Continue to apply sunscreen and (female patients) use mineral makeup to protect the treated areas.
- 3. Avoid exposure to excessive sun for up to 4 weeks. Hat or clothing must be used to protect the treated areas.
- 4. You may fully return to your normal exercise program.

### **SIDE EFFECTS**

Side effects are common with laser resurfacing, including the following:

- Erythema
  - Generally caused by increased blood flow to the area (which is not necessarily a bad thing).
  - Tends to resolve with the overall healing process but may be prolonged in certain patients.
  - Often correlated with depth of treatment and specific type of treatment device.
- Inflammation
  - Most people experience moderate swelling after treatment, but individual results vary.
  - The skin may feel tight because of tissue edema in combination with the actual skin-tightening effect of the laser. This effect may wax and wane depending on multiple variables (e.g., treatment depth, individual patient reaction).
- Allergic reactions: These usually occur in response to a specific medication or cream.
- Milia formation: These are usually the result of use of moisturizers or the injudicious use of irritant cleansers.
- Acne
  - Generally associated with the use of heavy emollients during the recovery period
  - Treated by changing topicals or adding oral antibiotics
  - Helpful to use Aquaphor because it is water based
- Scarring/keloids: This usually occurs because of some secondary factor (e.g., infection, scratching, poor wound care) that interferes with healing.
- Xerosis (dry skin): This is very common because we are effectively denuding the protective epithelial covering and allowing for greater evaporative water loss from the skin.
- Desquamation: Although most patients tend to have some degree of peeling, this is variable and depends on a number of factors, including depth of treatment, skin quality, and so forth.
- Pruritus: Although many patients experience some degree of itching that reflects the normal healing process, watch for severe or protracted pruritus because it can herald a more worrisome underlying etiology.

### **COMPLICATIONS**

Complications after laser resurfacing can occur as early as the initial healing phase or as late as several months after the procedure. As such, it is important to educate your patients about signs of an impending complication and ask them to notify the office if they suspect such. The most common complications include the following:

- Infection
  - Bacterial: Usually seen as adherent yellow crusting papules or increased pain/delayed healing.
  - Viral (herpes simplex virus): Watch for clustered vesicles, although herpes simplex virus infection can have an unusual presentation in the denuded epidermis within a few weeks after treatment.
  - Yeast: Symptoms may be subtle and often present simply as increased redness or itching (sometimes confused with contact dermatitis).
- Pigmentary changes
  - Although the incidence of pigmentary changes has dramatically decreased with the use of fractional laser resurfacing, pigmentary changes can still occur and steps should be taken before, during, and after treatment to prevent such changes, as well as to identify individuals at higher risk for both hypopigmentation and hyperpigmentation.

Contributing factors include the following:

Fitzpatrick skin types IV to VI

Prior history of pigmentary changes

More aggressive treatment settings

Treatment options

Prevention is the key.

Identify increased risk before treating higher Fitzpatrick skin types.

Pretreatment (e.g., Tri-Luma) is helpful.

Post-treatment protocol generally involves a combination of glycolic acid and hydroquinone.

- Delayed wound healing
  - Have high suspicion for potential underlying infection
  - Greater association with more aggressive treatment options
  - Increases potential risk for localized scarring
- Most important ways to minimize or potentially prevent complications
  - Patient education
  - Good pretreatment and post-treatment care
  - Early recognition of future problems during the initial consultation
  - Early recognition of issues during the healing period and prompt intervention

# LASERS AND PULSED-LIGHT DEVICES: LEG TELANGIECTASIA\*

Mitchel P. Goldman

Lasers and intense pulsed light (IPL) are used to treat leg telangiectasia for various reasons. *First*, both treatments have a futuristic appeal, not only to the general public but to physicians. By virtue of their advanced technology, they are perceived as state-of-the-art treatment modalities and are sought by the general public because "high tech" is thought of as safer and better than traditional sclerotherapy. Unfortunately, these perceptions have often resulted in unanticipated adverse sequelae (scarring and pain) at an increased cost to the patient (lasers cost considerably more to purchase and maintain than a needle, syringe, and sclerosing solution).

Second, lasers may have theoretical advantages compared with sclerotherapy for treating leg telangiectasia. Sclerotherapy treatment of leg veins has been associated with pigmentation in up to 30% of patients, the development of new blood vessels in up to 10% of patients, and, very rarely, allergenic reactions. These temporary but bothersome adverse effects are perceived not to occur with laser treatment. This chapter discusses the author's experience in treating leg veins with sclerotherapy, lasers, and IPL since 1983.

### MECHANISM OF ACTION FOR LASERS AND INTENSE PULSED LIGHT

Lasers and IPL are pulsed so that they act within the thermal relaxation times of blood vessels to produce specific destruction of vessels of various diameters based on the pulse duration (Table 54-1). Lasers of various wavelengths and broad-spectrum IPL are used to selectively treat blood vessels by taking advantage of the difference between the light absorption of the components in a blood vessel (oxygenated hemoglobin, deoxygenated hemoglobin, and methemoglobin) and the overlying epidermis and surrounding dermis to selectively thermocoagulate blood vessels. Deoxygenated hemoglobin has distinct optical properties, with two absorption spectrum peaks at approximately 545 and 580 nm, and a broader peak beyond 650 nm (Fig. 54-1). The main feature to note in the curve is the strong absorption at wavelengths below 600 nm, with less absorption at longer wavelengths. This is because the absorption coefficient in blood is higher than that of surrounding tissue for wavelengths between 600 and 1064 nm.

The goal is to deliver sufficient energy to thermocoagulate the target vessel, while the overlying epidermis and perivascular tissue remains unharmed. To accomplish this selective preservation of tissue, some form of epidermal cooling is also required. A number of different laser and IPL systems have been developed toward this end.

An understanding of the appropriate target vessel for each laser or IPL device is important so that treatment is tailored to the appropriate target. As detailed in sclerotherapy textbooks, most telangiectases arise from reticular veins. Therefore, the single most important concept to keep in mind is that feeding reticular veins must be treated completely before treating telangiectasia. This minimizes adverse sequelae and enhances therapeutic results. Failure to treat feeding reticular veins and short follow-up periods after the use of lasers may give inflated values to the success rates of laser treatment.

### HISTOLOGY OF LEG TELANGIECTASIA

The choice of proper wavelength(s), degree of energy fluence, and pulse duration of light exposure are all related to the type and size of target vessel treated. *Deeper vessels* necessitate a longer wavelength to allow penetration. *Large-diameter vessels* necessitate a longer pulse duration to effectively thermocoagulate the entire vessel wall, allowing sufficient time for thermal energy to diffuse evenly throughout the vessel lumen. The correct choice of treatment parameters is aided by an understanding of the histology of the target telangiectasia.

Venules in the upper and middle dermis typically maintain a horizontal orientation. The diameter of the postcapillary venule ranges from 12 to 35  $\mu m$ . Collecting venules range from 40 to 60  $\mu m$  in the upper and middle dermis and enlarge to 100 to 400  $\mu m$  in diameter in the deeper tissues. Histologic examination of simple telangiectases demonstrates dilated blood channels in a normal dermal stroma with a single endothelial cell lining, limited muscularis, and adventitial layers. Most leg telangiectases measure from 26 to 225  $\mu m$  in diameter. They are found 175 to 382  $\mu m$  below the stratum granulosum. The thickened vessel walls are composed of endothelial cells covered with collagen, elastic, and muscle fibers.

### **REVIEW OF AVAILABLE LASERS**

Patients seek treatment for leg veins mostly for cosmetic reasons. Any effective treatment should be relatively free of adverse sequelae.

# Krypton Triphosphate and Frequency-Doubled Nd-YAG (532 nm)

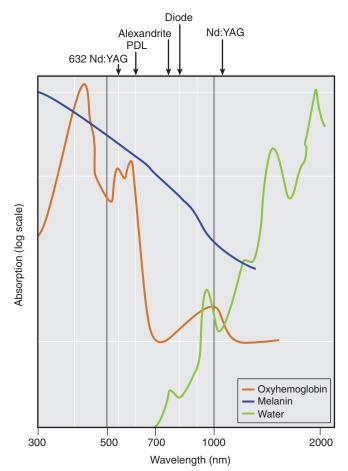

Modulated krypton triphosphate lasers have been reported to be effective at removing leg telangiectases using pulse durations between 1 and 50 msec. The 532-nm wavelength is one of the hemoglobin absorption peaks. Although this wavelength does not penetrate deeply into the dermis (about 0.75 mm), relatively specific damage (compared with argon laser) can occur in the vascular target by selection of an optimal pulse duration, enlargement of the spot size, and addition of epidermal cooling (Fig. 54-2).

<sup>\*</sup>Portions of this chapter are excerpted from Goldman MP, Bergan JB, Guex JJ: Sclerotherapy: Treatment of Varicose and Telangiectatic Leg Veins, 4th ed. London, Mosby, 2006.

TABLE 54-1 Thermal Relaxation Times of E Vessels	Blood
Diameter (mm)	Seconds
0.1 0.2 0.4 0.8 2.0	0.01 0.04 0.16 0.6 4.0

Effective results have been achieved by tracing vessels with a 1-mm projected spot. Typically the laser is moved between adjacent 1-mm spots following the vessels at 5 to 10 mm/sec. Immediately after laser exposure, the epidermis is blanched. Lengthening of the pulse duration to match the diameter of the vessel is attempted to optimize treatment.

We and others have found the *long-pulse 532-nm laser* (*frequency-doubled Nd:YAG*) to be effective in treating leg veins less than 1 mm in diameter that are not directly connected to a feeding reticular vein. When used with a 4° C chilled tip, a fluence of 12 to 15 J/cm² is delivered as a train of pulses in a 3- to 4-mm diameter spot size to trace the vessel until spasm or thrombosis occurs. Some overlying epidermal scabbing is noted, and hypopigmentation is not

**Figure 54-1** Oxygenated and deoxygenated hemoglobin. Water and melanin absorption curves are given as a function of wavelength. uncommon in dark-skinned patients. Although individual physicians report considerable variation in results, usually more than one treatment is necessary for maximum vessel improvement, with only rare reports of 100% resolution of the leg vein. Efficacy is technique dependent, with the potential for achieving excellent results. Patients need to be informed of the possibility of prolonged pigmentation at an incidence similar to that with sclerotherapy as well as temporary blistering and hypopigmentation that is predominantly caused by epidermal damage in pigmented skin (type III or above).

### Pulsed-Dye Laser (585 or 595 nm)

The *pulsed-dye laser* (*PDL*) has been demonstrated to be highly effective in treating cutaneous vascular lesions consisting of very small vessels, including port wine stains (PWSs), hemangiomas, and facial telangiectasia. The depth of vascular damage is estimated to be 1.5 mm at 585 nm and 15 to 20 µm deeper at 595 nm. Consequently, penetration to the typical depth of superficial leg telangiectasia may be achieved. However, telangiectases over the lower extremities have not responded as well, with less lightening and more post-treatment hyperpigmentation. This may be due to the larger diameter of leg telangiectases compared with dermal vessels in PWSs and larger-diameter *feeding* reticular veins, as described previously.

Figure 54-3 Red telangiectasia. A, Before treatment. B, After treatment. (Courtesy of Khalil A. Khatri, MD, Skin and Laser Surgery Center of New England, Nashua, NH, and Palomar Medical Technologies, Inc., Burlington, Mass.)

Vessels that should respond optimally to PDL treatment are red telangiectases less than 0.2 mm in diameter, particularly those vessels arising as a function of telangiectatic matting after sclerotherapy (Fig. 54-3). This is based on the time of thermocoagulation produced by this relatively short-pulse laser system (see Table 54-1).

In an effort to thermocoagulate larger-diameter blood vessels, pulse duration of PDL has been lengthened to 1.5 to 40 msec and the wavelength increased to 595 nm. This theoretically permits more thorough heating of a larger vessel. These longer pulse durations are created by using two separate laser beams each emitting a 2.4-msec pulse. These lasers operate at 595 nm with an adjustable pulse duration from 0.5 to 40 msec delivered through a 5-, 7-, or 10-mm diameter spot size or a 3  $\times$  10-mm or 5  $\times$  8-mm diameter elliptical spot. Dynamic cooling with cryogen spray is also available, with the cooling spray adjustable from 0 to 100 msec given 10 to 40 msec after the laser pulse or as continuous 4° C air cooling at a variable speed. A fluence of 10 to 25 J/cm² can be delivered through a 3  $\times$  10-mm or 5  $\times$  8-mm diameter spot.

We use the PDL at pulse durations matching the thermal relaxation time of the leg veins. The energy fluence used is just enough to produce vessel purpura or spasm. We use stacked pulses to achieve this clinical end point. Because of the necessity for multiple treatments and the significant occurrence of long-lasting hyperpigmentation, we reserve the use of PDL for sclerotherapy-resistant red telangiectases less than 0.2 mm in diameter.

### **Diode Lasers**

Multiple diode-pumped lasers are now available, including 532-nm, 810-nm, 915-nm, and 940-nm lasers (Table 54-2). Diode lasers generate coherent monochromatic light through excitation of small diodes. As a result, these devices are lightweight and portable with a relatively small desktop footprint. Diode laser therapy is more painful than sclerotherapy in almost all patients, with equal efficacy noted by the patients who had had both sclerotherapy and laser treatment. A combination diode laser at 915 nm with radiofrequency at levels up to 100 J/cm² has been used to treat leg telangiectasia.

Diode lasers are limited by treatment pain and adverse effects. Of note, unless feeding reticular veins are treated, the distal treated telangiectases recur at 6 to 12 months post-treatment. Some authors appear to be able to achieve better results than others using similar parameters. The addition of radiofrequency to the diode appears to offer little advantage.

### **Intense Pulsed Light**

The high-intensity pulsed light source was developed as an alternative to lasers to maximize efficacy in treating leg veins (PhotoDerm VL; ESC/Sharplan, now Lumenis, Santa Clara, Calif). This device permits sequential rapid pulsing, longer-duration pulses, and longer

penetrating wavelengths than other laser systems. Theoretically, a phototherapy device that produces a noncoherent light as a continuous spectrum longer than 550 nm should have multiple advantages over a single-wavelength laser system. First, both oxygenated and deoxygenated hemoglobin absorb light at these wavelengths. Second, blood vessels located deeper in the dermis are affected. Third, thermal absorption by the exposed blood vessels should occur with less overlying epidermal absorption because the longer wavelengths penetrate deeper and are absorbed less by the epidermis.

With the theoretical considerations just mentioned, IPL emitting in the 515- to 1000-nm range was used at varying energy fluences (5 to 90 J/cm<sup>2</sup>) and various pulse durations (2 to 25 msec) to treat venectases 0.4 to 2.0 mm in diameter. Clinical trials using various parameters with the IPL, including multiple pulses of variable duration, demonstrated efficacy ranging from over 90% to total clearance in vessels less than 0.2 mm in diameter, 80% in vessels 0.2 to 0.5 mm, and 80% in vessels 0.5 to 1 mm in diameter. The incidence of adverse sequelae is minimal, with hypopigmentation occurring in 1% to 3% of patients and resolving within 4 to 6 months. Tanned or darkly pigmented Fitzpatrick type III patients are more likely to develop hypopigmentation and hyperpigmentation in addition to blistering and superficial erosions. The choice of a cut-off filter is based on skin color, with light-skinned patients using a 550-nm filter and darker-skinned patients using a 570- or 590-nm filter.

The use of IPL to treat leg veins has produced encouraging results, but these are far from being easily reproduced. This technology requires significant experience and surgical ability to produce good results. Various parameters must be matched to the patient's skin type as well as to the diameter, color, and depth of leg vein. With older machines that do not have integrated cooling through sapphire crystals, a cold gel must be placed between the IPL crystal and skin surface to provide optimal elimination of epidermal heat. There are now dozens of IPL units available from many different manufacturers (see Table 54-2).

### Long-Pulse Nd:YAG Laser (1064 nm)

The 1064-nm Nd:YAG laser is probably the most effective laser available to treat leg telangiectasia. In an effort to deliver laser energy to the depths of leg veins (often 1 to 2 mm beneath the epidermis) with thermocoagulation of vessels 1 to 3 mm in diameter, 1064-nm lasers with pulse durations between 1 and 250 msec have been developed. However, because of the poor absorption of deoxygenated and oxygenated hemoglobin with a 1064-nm wavelength, higher fluences must be used. Depending on the amount of energy delivered, the epidermis must be protected to minimize damage to pigment cells and keratinocytes (Fig. 54-4). Three mechanisms are available to minimize epidermal damage through heat absorption. First, the longer the wavelength, the less energy will be absorbed by

melanocytes or melanosomes. This will allow darker skin types to be treated with minimum risks to the epidermis because of decreased melanin interaction. *Second*, delivering the energy with a delay in pulses greater than the thermal relaxation time for the epidermis (1 to 2 msec) allows the epidermis to cool conductively between pulses. This cooling effect is enhanced by the application of cold gel on the skin surface that conducts epidermal heat away more efficiently than air. *Finally*, the epidermis can be cooled directly to allow the photons

to pass through without generating sufficient heat to cause damaging effects.

Epidermal cooling can be provided in many different ways. The simplest method is continuous contact cooling with chilled water that can be circulated in glass, sapphire, or plastic housings. The laser impulse is given through the transparent housing that should be constructed to ensure that the laser's effective fluence is not diminished. This method is referred to as continuous contact cooling.

**Figure 54-4** Large leg veins. **A,** Before treatment, **B,** After treatment. (Courtesy of Palomar Medical Technologies, Burlington, Mass.)

Its benefit lies in its simplicity. The disadvantage is that the cooling effect continues throughout the time that the cooling device is in contact with the skin. This results in a variable degree and depth of cooling determined by the length of time the cold housing is in contact with the skin. This nonselective and variable depth and temperature of cooling may necessitate additional treatment energy so that the cooled vessel will heat up sufficiently to thermocoagulate.

Another method of cooling is *contact precooling*. In this approach, the cooling device contacts the epidermis adjacent to the laser aperture. The epidermis is precooled and then treated as the handpiece glides along the treatment area. Because the cooling surface is not in the beam path, no optical window is required and better thermal contact can be made between the cooling device and the epidermis. The drawback is the nonreproducibility of cooling levels and degrees, which are based on the speed and pressure with which the practitioner uses the contact cooling device.

Yet another method for cooling the skin is to deliver a *cold spray* of refrigerant to the skin that is timed to precool the skin before laser penetration and also to postcool the skin to minimize thermal back-scattering from the laser-generated heat in the target vessel. This method along with continuous air cooling reproducibly protects the epidermis and superficial nerve endings. In addition, it acts to decrease the perception of thermal-laser epidermal pain by providing another sensation (cold) to the sensory nerves. Finally, it allows for efficient use of laser energy because of the relative selectivity of the cooling spray, which can be limited to the epidermis.

Because the target vessel poorly absorbs 1064-nm wavelength, a much higher fluence is necessary to cause thermocoagulation. Whereas a fluence of 10 to 20 J/cm² is sufficient to thermocoagulate blood vessels when delivered at 532 or 585 nm, a fluence of 70 to 150 J/cm² is required to generate sufficient heat absorption at 1064 nm. Various 1064-nm lasers are available that meet the criteria for selectively thermocoagulating blood vessels (see Table 54-2). All long-pulse 1064 nm Nd:YAG lasers are not the same. Variables include the spot size, laser output (in both fluence and how the long laser pulse is generated), pulse duration, and epidermal cooling.

I have found the 1064-nm, long-pulse Nd:YAG lasers to be beneficial in the treatment of leg telangiectasia not responsive to sclerotherapy or other lasers. The advantage of using a 1064-nm laser is that its longer wavelength can penetrate more deeply, allowing effective thermosclerosis of vessels up to 3 to 4 mm in diameter. In addition, the 1064-nm wavelength permits treatment of patients of skin types I to VI, with or without a tan, because melanin absorption is minimal. The 1064-nm, long-pulse laser systems are not entirely without side effects. Cutaneous burns with resulting ulcerations, pigmentation, and telangiectatic matting have been observed with each of these systems as parameters are being tested. The dynamically cooled, 1064-nm Nd:YAG laser appears to produce the best clinical resolution with the least pain and adverse effects.

# Combination/Sequential 595-nm Pulsed-Dye Laser and 1064-nm Nd:YAG (Cynergy)

The latest laser to enter the market uses a novel sequential 595-nm PDL pulse followed by a 1064-nm Nd:YAG laser pulse. The rationale for enhanced efficacy is that the 595-nm pulse generates methemoglobin, which is more strongly absorbed by 1064-nm wavelengths. Lower energies from both lasers can therefore be used, with the possibility of less pigmentation and adverse sequelae. Preliminary experience is promising in treating bright red vessels less than 0.1 mm in diameter, which are the most difficult vessels to treat with sclerotherapy.

### **CONCLUSIONS**

Because sclerotherapy is still considered to be more effective than laser vein therapy and is relatively cost effective compared with laser or IPL treatment, when is it appropriate to use this advanced therapy? Obviously, needle-phobic patients will tolerate the use of this technology even though the pain from lasers and IPL is more intense than that of sclerotherapy with all but hypertonic solutions. Patients who are prone to telangiectatic matting from injected sclerosants are also appropriate candidates. Vessels below the ankle are particularly appropriate to treat with light because sclerotherapy has a relatively high incidence of ulceration in this area owing to the higher distribution of arteriovenous anastomoses. Finally, patients who have vessels that are resistant to sclerotherapy are excellent candidates. A 75% clearance rate with two to three IPL treatments has been documented in sclerotherapy-resistant vessels.

The optimal treatment plan for common leg telangiectasia includes sclerotherapy to treat the feeding venous system and laser or IPL to seal superficial, very tiny vessels to prevent extravasation with resulting pigmentation, recanalization, and telangiectatic matting.

### LASERS: TATTOO REMOVAL

Kevin Crawford

Decorative tattoos have been a part of human history for thousands of years (Fig. 55-1). The recent discovery of a tattooed, 5000+-year-old, frozen, early European in a glacier in Italy clearly supports this fact. If tattoos have been placed in the skin for over 5000 years, clinicians have likely been trying to remove them for the same amount of time.

It is estimated that 50% or more of all people with tattoos will eventually want them removed completely. Approximately 40% of all tattoo removal patients do *not* want to remove all of the tattoo ink. They in fact desire only to change the existing tattoo and have a new tattoo placed over the old tattoo.

### **TATTOO TYPES**

Amateur tattoos or home tattoos are usually black tattoos based on "India ink." The carbon-based India ink dyes are, fortunately, the easiest to safely remove. Amateur tattoos are often placed in the dermis by simply dipping the end of a needle into the ink and then dotting the skin to form a design or pattern. The depth of the ink in the dermis is very imprecise. Therefore the density and uniformity of the ink in the design are often very uneven (Fig. 55-2).

Professional tattoos are placed using a repetitively oscillating needle, which in skilled hands will place the ink at a relatively consistent depth in the dermis. Uniform depth can be an advantage for the removal process; therefore, one would think that professional tattoos would have a more consistent removal success rate. However, with professional tattoos, the various colors and the density of the ink complicate the removal process (Fig. 55-3).

Cosmetic tattoos or permanent cosmetics such as lip liners, eyelid liners, and eyebrow color enhancement pose unique challenges when being removed because of location and variety of mixed colors (Fig. 55-4).

Traumatic tattoos are most often the result of an explosion (gunpowder embedded in the skin) or a bicycle or motorcycle accident (asphalt/tar embedded in the skin). Scar tissue often surrounds the embedded particles. The particles are not too deep and can usually be easily removed with a quality-switching (QS) laser (Fig. 55-5).

### **NEW TATTOO PIGMENTS**

Ink recently developed by Freedom-2, Inc., LLC,\* if accepted by the tattoo community, will be much easier to remove. In my area, there are approximately 500 tattoo artists. Many have expressed their reluctance to make tattoos a temporary expression of their art, but may use it for some tattoos (e.g., for names). Freedom-2 ink's microencapsulated biocompatible materials address concerns related to

adverse skin responses, allergic reactions, infections, inflammation, and adverse systemic reactions. The application of Freedom-2 ink is consistent with today's tattoo technology. However, Freedom-2 ink consists of safe, resorbable pigments microencapsulated in clear, stable polymer beads. Freedom-2 ink can be easily and quickly removed using current laser technology in a much more effective manner than current permanent ink options (see later).

### **CONTRAINDICATIONS**

### **Absolute**

- Pregnancy
- Breast-feeding
- Known allergy to pigment
- Uncontrolled systemic disease
- Active untreated bacteria or viral infection
- Use of Accutane in preceding 6 months (this is a matter of debate among many)
- Immunosuppressive disorder

### Relative

- Scarring abnormalities
- Bleeding abnormalities
- Hepatitis
- Poorly controlled diabetes mellitus
- Peripheral vascular disease
- Seizure disorder
- Client expectations unreasonable

### FORMER TREATMENT METHODS

Until recently, all tattoo removal modalities resulted in disfiguring scars. In the past, the most popular options included salabrasion (salt-based dermabrasion), mechanical dermabrasion,  $\mathrm{CO}_2$  laser ablation, and infrared photocoagulation.

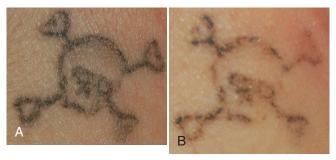

### LASER TREATMENT AND REMOVAL

Fortunately, the majority of tattoos are still predominantly composed of *black* ink. However, vibrant colors are becoming more popular and are more difficult to remove. There are three common QS lasers that are frequently used for removing tattoos: the *q-switched ruby laser* (QSRL; 694-nm red), the *q-switched Nd:YAG laser* (QSYL; both 1064-nm infrared and 532-nm [FD-QSYL] green wavelengths), and the *q-switched alexandrite* (QSAL; 755-nm red) laser. *Quality-switching* (QS), sometimes known as *giant pulse formation*, is a technique by which a laser can be made to produce a pulsed output beam. The technique allows the production of light pulses

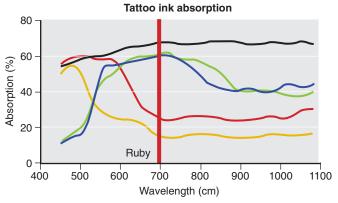

Figure 55-6 Various wavelengths and absorption of different ink colors.

# **TABLE 55-1** Laser Characteristics for Removal of Different Tattoo Ink Colors

Ink Color	Laser Characteristics*
New black or dark blue	1064 nm, 6 mm, 1.0–2.0 J
Faded black or dark blue	1064 nm, 4–6 mm, 3.0–6.4 J
Red/orange/purple	532 nm, 3 mm, 2.0–3.5 J
Faded red/orange/purple	532 nm, 3–4 mm, 2.0–4.0 J
Green	650 nm, 2 mm (preset)
Sky blue	585 nm, 2–3 mm (preset)

<sup>\*</sup>Wavelength (nm), spot size (mm), energy level (J).

with extremely high (gigawatt) peak power, much higher than would be produced by the same laser if it were operating in a continuous-wave (constant output) mode.

All three of these lasers have strong absorption by black ink. The color of the ink will determine the wavelength of laser needed (Fig. 55-6). The amount or density of the ink and the depth of the ink will determine the approximate number of treatments required. The QSYL has been the dominant laser used for removing tattoos. QSYLs, by design, produce shorter, higher peak power pulses than either QSRL, and the QSYL can also produce two very useful output wavelengths. The MultiLite Dye Laser Handpieces, compatible with HOYA ConBio Revlite and C6 lasers, convert the 532-nm wavelength to either 585 nm or 650 nm, effectively offering two additional wavelengths. Candela's AlexTriVantage offers the "Laser-Pumped-Laser" technology with new handpieces that convert the 755-nm wavelength to 532 nm or 1064 nm to improve removal of "all tattoo colors." The choice of an appropriate laser may depend on the prevalence of the type/color of the majority of the tattoos seen in the practice. The QSYL has become popular because of its ability to treat black, red, orange, and blue inks. The QSYL pulses faster than the ruby- or alexandrite-based laser, so more surface area can be treated in less time.

### **TREATMENT PROTOCOL**

- For a given color of ink, choose the most appropriate laser based on wavelength and other characteristics (Table 55-1).
- Cleanse area of any makeup.
- Laser tattoo removal is painful. Clinicians may decide to apply a topical anesthetic with or without occlusion. If this is the case, the topical anesthetic cream must be applied for approximately 45 minutes to 1 hour before commencing treatment (see Chapter 5, Local and Topical Anesthetic Complications). As an alternative to anesthetic creams, a flexible gel ice pack may be used. Apply ice packs for approximately 30 to 45 seconds before laser treatment. Use caution not to freeze the skin.
- Limit the treatment area for any given treatment session. Normally the largest area treated at a given time is 24 to 30 square inches.

If the tattoo area is larger, the client may come in biweekly to treat additional portions, so that the entire tattoo can be treated every 6 to 10 weeks.

- Begin your treatment with the 1064-nm wavelength to treat the dark ink in the tattoo. The surface of the skin should turn a mild "hazy white" color each time the laser pulse strikes the skin. Some slight overlap is acceptable from pulse to pulse, but it is not advisable to repeatedly cover the same area because once the skin turns "white" it reflects subsequent laser pulses.
- After the completion of the pass over the black ink in the tattoo, the *red ink* can be treated with the 532-nm wavelength of the QSYL. As with the 1064-nm wavelength, the 532-nm pulses are applied evenly to the red areas of the tattoo until there is "white" color covering the entire treated area (Fig. 55-7).

**NOTE:** Treating with 532 nm first will cause the skin to reflect the 1064-nm wavelength, minimizing the success in treating the black ink.

Start off with a lower power setting. There are no "set" parameters
to use with tattoo removal as to joules/power, just a range. Setting
knowledge comes with time and experience (see Table 55-1).

### **COMMON ERRORS**

- Overtreatment does not increase the speed of clearance of the tattoo and only increases the risks of negative side effects. It should be noted that it is very common for red ink to blister after treatment
- In the mid-1990s, *latex-based tattoo ink* was introduced. This ink is vibrant from the first day it is placed in the dermis, and the bright colors remain "glossy." During the initial evaluation the tattoo appears to have the appearance of high-gloss, oil-based paint. *This ink cannot be removed by any laser*. This ink "shrinks" when heated with a laser, causing deep ulcerations that take months to heal and almost certainly resulting in deep, depressed scars.
- "Cosmetic" tattoos pose other problems. Generally, cosmetic tattoos are black or dark red and are used to accentuate margins or borders. They include lip liners, eyelid liners, and eyebrow appearance enhancement. When treated with a high-powered QS laser, oxidation occurs and the ink turns black. When the red lip or eye liner changes to a black lip or eye liner, it is very disconcerting for the patient. The black ink tattoo can be removed and should be treated as any other black ink tattoo. In general, cosmetic tattoos can be effectively cleared; however, care and a thorough consultation are very important
- Color changes in dyes: titanium dioxide is a white ink that, when
  exposed to a QS pulse of light, can turn black. Gold atoms in some
  inks can change from gold to purple to black depending on the
  oxidation state change. Again, subsequent treatments usually are
  successful in removing the changed ink color, but it is very disturbing to the patient to have the tattoo dramatically change
  color.

Figure 55-7 Before (A) and during (B) treatment of red ink tattoo with Palomar Q-YAG 5, 1.5 J, 4-mm spot size, blended 1064/532 nm.

### **POSTPROCEDURE CARE**

- Normally there is erythema and edema immediately after treatment. Provide an ice pack/ice pillow after treatment to remove the heat from the treated area and reduce post-treatment discomfort.
- Ointments such as Aquaphor are applied to the treated area, which is covered if desired. If epidermal damage does occur, use topical ointments for moist healing to prevent scabbing of the wound (see patient education form for Chapter 30, Radiofrequency Surgery [Modern Electrosurgery], online at www. expertconsult.com).
- In addition to the proper wound care, sun exposure prevention of the treated area is very important. Because the treated area has been traumatized by the laser pulses, the skin is more sensitive to hyperpigmentation by exposure to the sun. Encourage SPF 45 use during the entire treatment period. The accepted treatment interval is 6 weeks.
- Follow-up treatments: some clinicians feel that waiting 2 months or even longer between treatment sessions may be advantageous. Generally, for amateur tattoos, most of the ink can be removed in three to five treatment sessions. Amateur, gang, and prison tattoos are generally easier to remove than professional tattoos. Professional tattoos, depending on the colors of ink, will take from 6 to 10 treatment sessions to remove. In rare instances, some professional tattoos require more than 10 treatments to be successfully removed.

### **COMPLICATIONS**

Although the treatment and removal of tattoos with QS lasers is considered a very safe procedure, potential side effects and risks do exist, including the following:

- Allergic reactions
- Blistering
- Infection
- Pain
- Swelling
- Scabbing
- Bleeding
- Itching
- Hypertrophic scarring
- Atrophic scarring
- Hyperpigmentation
- Hypopigmentation
- Incomplete tattoo removal
- Color changes in dyes

Allergic reactions to tattoo inks are occasionally seen. Red inks can produce very severe reactions in patients after QS laser treatments. After treatment of a red tattoo, in particular, patients often complain of itching. This is a sign of an allergic reaction to mercuric oxide in the tattoo ink. These patients should not be treated with a QS laser. Other, nondispersive methods of removal, such as surgical excision or erbium laser resurfacing, may be beneficial.

Although rare, hypertrophic and atrophic scarring are the most common complications associated with QS laser tattoo removal. In both cases, the scar formation can be attributed to overly aggressive treatment sessions or poor postoperative wound care by the patient. Keeping the wound clean and covered and preventing the wound from drying out and scabbing are of paramount importance. Conservative post-treatment wound care and strong patient compliance are the keys to preventing hypertrophic scarring.

Because tattoo ink density is always an unknown, the number of treatments necessary to completely remove a tattoo can only be estimated. Patients may become frustrated and impatient during the process. It is not uncommon to find tattoos or parts of tattoos that need greater than 10 treatment sessions, and some patients require 20 or more treatment sessions to remove very stubborn inks. As the number of treatment sessions increases, the degree of *dermal fibrosis* 

also increases and the texture of the skin changes as well. Patients need to be aware of this.

Postinflammatory hyperpigmentation (PIH) should be considered a transient side effect related to the impact of the high-intensity laser pulse. PIH may fade on its own after the initial treatment, but the need to perform 7 to 10 treatments will, on average, increase the risk of developing PIH. Patients with Fitzgerald skin types IV to VI are more likely to develop PIH and should be advised accordingly. During treatment, portions of the treated area may completely lose pigmentation. This is a more significant problem for darker skin types when treating colored tattoos. When the tattoo removal treatment is completed the treated area will exhibit hypopigmentation or depigmentation in the same shape as the tattoo that was removed, if the melanocytes are permanently disabled. If there are still active, nondamaged melanocytes in the treated area, it should slowly repigment after repeated sun exposure.

One of the most difficult problems to resolve is the "incomplete" removal of the tattoo. If the majority of the ink is removed in the first five or six sessions, then extending the intervals between sessions to 12 to 16 weeks will benefit the patient because it will permit more clearance of the ink to take place. At a certain point, further treatments will yield minimal, if any improvement and the decision to discontinue treatment can be made.

### **BOTULINUM TOXIN**

Edward M. Zimmerman

In 1978, a San Francisco ophthalmologist, Alan B. Scott, published the first paper on the use of botulinum toxin in humans. He used it to treat strabismus in 1980. The U.S. Food and Drug Administration  $\,$ (FDA) first approved botulinum A exotoxin (BTX-A or BoNT A) in 1989 for the treatment of strabismus and blepharospasm associated with dystonia, benign essential blepharospasm, and facial nerve (CN VII) disorders in patients 12 years of age or older. It is also used for primary hyperhidrosis of the axillae, palms, and soles, and for treatment of muscular tension headaches and urinary detrusor instability. In 2002, the FDA approved Botox Cosmetic for temporary alleviation of dynamic wrinkles of the glabellar area, and in 2004 Botox was approved for the treatment of primary axillary hyperhidrosis. All other uses are "off-label." This chapter discusses the cosmetic uses of BTX-A, which include the temporary alleviation of dynamic wrinkles of the face and neck; the lifting of nose tips, oral commissures, and brows; the thinning of hypertrophic masseter muscles; and smoothing the pebbly appearance of a "walnut" chin. Botox injections have become the most common cosmetic procedure in the world. Nearly 2.5 million vials of Botox Cosmetic were sold worldwide to perform 4.6 million cosmetic injections in 2008, a continued increase since it was introduced, despite current economic downturns.

BTX-A is available in several forms. Botox, *now called OnabotulinumtoxinA by the FDA*, is a purified neurotoxin complex produced by Allergan, Inc. (Irvine, Calif). It is available in 100-unit vials. Speywood Pharmaceuticals, Ltd., in Maidenhead, England, makes *Dysport* in 500-unit vials. It was FDA approved to be distributed in the United States as Dysport, or AbobotulinumtoxinA, by Medicis Pharmaceuticals (Scottsdale, Ariz). Botox is three to four times as potent per unit as Dysport. Pur-Tox, another BTX-A from Mentor Corporation (Santa Barbara, Calif), is expected to be FDA approved in 2010. Other, non–FDA-approved forms are available outside of the United States, including Xeomin in Germany, Neuronox in Korea, and Chinatox in China.

There are seven serotypes of BTX, designated A through G. Type A is the most potent, and it was the first one commercially available. BTX-A and BTX-E work at the level of the neuromuscular junction of striated muscle, where they irreversibly bind, and after cleaving 9 and 25 amino acids, respectively, from the C-terminus of the SNAP 25 protein, they inhibit the release of acetylcholine. This causes paralysis of that muscle until a new neuromuscular junction is sprouted by the nerve ending, a process that can take weeks to months depending on the density of innervation and on the site, amount, and concentration of the solution injected. The onset of muscle paralysis, reduced sweating, or pain control varies from site to site and patient to patient. Most patients notice a gradual increasing response in 3 to 7 days that plateaus and lasts for 2 to 11 months, with a gradual redevelopment of wrinkles, sweating, or pain. The duration of effect on sweating (6 to 9 months) is significantly longer than on wrinkles (3 to 4 months). Some patients respond more quickly and completely to the injections. A small percentage of patients are minimally responsive, even to large amounts of Botox. Some become resistant to injections. Resistance in patients treated

with less than 100 U per session for either blepharospasm or aesthetic purposes is rare. Patients who become resistant to BTX-A because of antibody development after repeated, large doses, and laboratory workers, who are specifically immunized, may respond to BTX-B and BTX-F, which are currently undergoing clinical trials. BTX-B (Myobloc, now called RimabotulinumtoxinB by the FDA) was approved by the FDA in December, 2000, for treatment of patients with cervical dystonia. It is produced by Solstice Neurosciences (South San Francisco, Calif). It has a rapid onset of action (hours to days), loses effect after about 6 to 12 weeks, and is currently used to treat cervical dystonia. BTX-A is about 50 times as potent as BTX-B.

### SAFETY OF BOTOX AND DYSPORT

The  $LD_{50}$  of Botox in humans is estimated to be 2500 to 3000 U of toxin for a 70-kg human, or approximately 40 U/kg. For cosmetic purposes, doses of Botox are limited to 100 U; therefore, Botox Cosmetic can be considered a safe and useful chemical. No irreversible clinical effects have been reported.

Similarly, the suggested limit for cosmetic uses of Dysport is 300 U, but up to 1000 U may be used to treat cervical dystonia if needed. No formal drug interaction studies have been conducted with Dysport. However, the package insert lists much the same suggested interactions as could occur with other types of BTX-A.

### **INDICATIONS**

### FDA-Approved Indications for Botox

- Strabismus
- Blepharospasm with dystonia
- Benign essential blepharospasm
- Cervical dystonia (spasmodic torticollis)
- Primary axillary hyperhidrosis
- Dynamic glabellar rhytids

### **FDA-Approved Indications for Dysport**

- Cervical dystonia
- Dynamic glabellar rhytids

### Other Indications for BTX-A

- · Cosmetic reduction of dynamic wrinkles in face, lips, and neck
- Hyperhidrosis of the palms, soles, and forehead
- Anal fissures resulting from an increase in rectal sphincter tone (see Chapter 96, Anal Fissure and Lateral Sphincterotomy and Anal Fistula)
- Headaches, both tension and migraine
- Asymmetric face, acquired (e.g., Bell's palsy, hemifacial spasm, or, after facial trauma, the unaffected side causes reduced movement or unopposed muscle tension)

Anecdotally, it is well accepted to perform superficial skin treatments (microdermabrasion, superficial peels, nonablative laser and light treatments) first and then administer BTX-A afterward on the same visit. Injections can also be performed after minor surgeries to different parts of the face (e.g., inject the glabella and brow after blepharoplasty) without causing a deficit in onset or duration of action of BTX-A. More invasive chemical peels, deeper laser resurfacing, and facelifts cause enough inflammation to decrease the duration of action of BTX-A. Injections are usually done 4 to 8 weeks after these procedures.

### **CONTRAINDICATIONS**

- Pregnancy.
- Preexisting neuromuscular diseases (this is a relative contraindication; consider obtaining a neurologist's opinion before initiating BTX-A for cosmetic reasons in these patients).
- Sensitivity or allergy to any of the constituents of reconstituted Botox (e.g., BTX-A, human albumin).
- Some medications decrease neuromuscular transmission and may potentiate the effect of large doses of BTX-A (usually not a problem for the small doses used for cosmetic procedures). These include aminoglycosides and similar antibiotics, neuromuscular blocking agents (succinylcholine), penicillamine, quinidine, and calcium channel blockers.
- Sun exposure has been shown to decrease the effect and duration of BTX-A injections.

### **EQUIPMENT**

- One vial of Botox (50 U or 100 U) or Dysport (300 U). These
  are labeled as "single use or single patient use," which some states
  (e.g., Nevada) are now enforcing—meaning single use on a single
  patient at a single time. For many years, physicians have reconstituted these drugs and then used separate, sterile syringes of
  medication on different patients for enhanced economy to the
  patient with no side effects or problems.
- Sterile normal saline without preservatives (single-dose vials).
   (Although not recommended by the company, saline with the preservative benzyl alcohol is commonly used to reconstitute Botox. This solution stores safely in a refrigerator for several weeks and may be less painful to inject because of the numbing effect of the preservative.)
- 20-gauge needle to reconstitute the vial of Botox with saline.
- 1-mL syringes and 30-gauge, ½-inch needles for injection, or 0.3-mL insulin syringes with 30- or 31-gauge needles
- Alcohol wipes to cleanse injection sites (optional)
- Facial tissues or clean gauze to hold pressure on injection sites
- Nonsterile gloves to wear during injection
- Ice packs or small bags of ice to topically anesthetize the skin and constrict blood vessels at injection sites before injection

### PREPROCEDURE PATIENT PREPARATION

Botox is delivered by overnight transport in a thick Styrofoam container packed with dry ice to keep the potent toxin stable. Allergan recommends storage of the unmixed toxin at 5° C or lower (frozen). Potency of the toxin is measured in units (U), where 1 U is the amount of toxin that kills 50% (LD50) of a standardized mouse model when injected intraperitoneally. Each vial of Botox contains either 50 U or 100 U of toxin, plus 0.5 mg of human albumin and 0.9 mg of sodium chloride. The toxin is lyophilized and sealed in the vial under negative pressure.

Dysport is supplied in a single-use, sterile vial for reconstitution intended for intramuscular injection. Each vial contains 500 U or 300 U of lyophilized abobotulinumtoxinA, 125  $\mu g$  human serum albumin, and 2.5 mg lactose. Dysport may contain trace amounts of cow's milk proteins.

The FDA-recommended dose for treatment of dynamic glabellar rhytids with Botox is 20 U, compared with the recommended dose of 50 U for Dysport.

BTX-B (Myobloc) is delivered premixed in several quantities: 2500 U in 0.5 mL, 5000 U in 1 mL, and 10,000 U in 2 mL. (BTX-B may be stored undiluted in the refrigerator at  $2^{\circ}$  C to  $8^{\circ}$  C for up to 21 months. If diluted, it should be used promptly because it contains no preservatives.)

An injection site record (Fig. 56-1) should be available before the procedure begins.

## RECONSTITUTION AND HANDLING OF BOTOX AND DYSPORT

Alcohol used to cleanse the rubber stoppers and injection sites can inactivate the toxin. Allow it to evaporate completely before proceeding. Allergan recommends that from 1 to 10 mL of sterile saline without preservatives (single-dose vials do not contain preservatives see previous comment) be mixed in the vial of Botox, using the large needle to reconstitute it. A vial that does not demonstrate a vacuum should not be used and will be replaced by the company. The reconstituted Botox should be mixed by gently rolling or swirling the vial. Shaking the vial (i.e., causing foaming) was thought to denature Botox, leading to decreased potency of the solution, but this has proven not to be an issue. Once reconstituted, the toxin should be kept at 2° C to 8° C (refrigerated) and used as quickly as possible. Practitioners may choose to store the solution in the glass vial and use a larger needle to fill the solution into 1-mL syringes as needed or remove the rubber stopper and withdraw the fluid with the small needle on insulin syringes to inject the solution. The package insert recommends using this "single-use vial" of toxin within 4 hours when mixed with sterile saline without preservatives. Group consensus and studies have shown minimal loss of potency in either refrigerated or frozen solution made with saline, with or without preservatives, at 30 days. However, most patients agree that injections reconstituted with saline with preservatives are more comfortable.

Botox dilution varies by use and personal preference. More concentrated dilutions seem to cause effects sooner, but may be more difficult for a clinician to inject accurately and last no longer than injections of more dilute solutions. Most clinicians dilute 100 U of lyophilized Botox with 1 to 6 mL of saline. Dilutions of 100 U/1 mL (10 U/0.1 mL), 100 U/2 mL (5 U/0.1 mL), or 100 U/3 mL (3.3 U/0.1 mL) are commonly used for cosmetic procedures, headache treatments, and hyperhidrosis (Table 56-1). The area of effect associated with each injection point can be up to 2 to 3 cm in diameter.

Dysport can be reconstituted with 1 to 3 mL of saline, depending on the clinician's preference, and used in a similar fashion.

### **PATIENT EDUCATION**

Before injection, the patient should review and sign the informed consent (see the patient consent form online at www.expertconsult. com). The patient should appreciate that the treatment produces temporary results (3 to 4 months) and will take up to 10 days for the full effect. The FDA has recently added a revised form, included with the BTX-A vial, for patient distribution every time BTX-A injections are to be given. It discusses the risk of "potentially life threatening distant spread effects after local injection" because these injections have become so commonplace that some patients may underestimate the associated risk. Conversely, by minimizing the amount of toxin used (to decrease risk of side effects), some wrinkles may not be totally eradicated. However, a "natural" rather than "frozen" face is aesthetically desirable. Efficacy and duration of action vary from patient to patient, but both generally increase with serial injections over time as a result of increasing muscle atrophy. At times, a "touch up" could be of value 2 to 3 weeks after the initial

injections, should there be areas where the muscles have not been affected enough or with bilateral symmetry.

Caution the patient against prior use of aspirin, large doses of vitamin E, garlic, ginger, and diet pills, which increase the risk of bruising. Cosmetics covering treatment areas can be removed just

TABLE 56-I Dilutions of Botox (100 Units/Bottle as Supplied) Amount of Saline (mL) Units/0.1 mL Units/I mL 10 100 50 2 5 3 3.3 33 25 2.5 2.0 20

before injection and reapplied immediately after, provided the patient *does not rub the treatment areas afterward*. Rubbing the treatment areas can spread the Botox into areas not intended for treatment, increasing the risk of complications such as ptosis. Conversely, the clinician may massage Botox toward or away from areas intentionally.

### **TECHNIQUE**

Cosmetic uses for Botox and Dysport include the following:

- Forehead wrinkles caused by frontalis muscle contraction
- Glabellar (frown or "11") lines and ridges across the bridge of the nose caused principally by corrugator and procerus contraction
- "Bunny lines" formed across the upper nose (the expression of nose scrunching when someone smells something foul) caused by nasalis muscle contraction

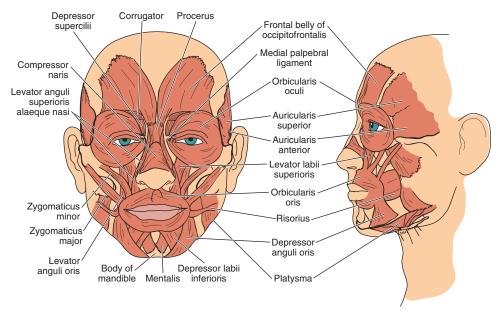

Figure 56-2 Anatomy of the face with masseter muscles noted.

- Lateral crow's feet, inferior eyelid wrinkles, and ptotic eyebrows from orbicularis oculi tension
- Lipstick lines from orbicularis oris contraction; chin clefting and elevation from overactive mentalis muscles
- Depressed lateral commissures from overactive depressor anguli
- Ptotic nose tips and "gummy smiles" caused by depressor septi nasi and levator labii superioris muscle contraction
- Masseter hypertrophy that causes lower face broadness and even neck bands from overactive platysma (Fig. 56-2)

Treatment of any site starts with appropriate patient selection, education, and consent. Injections are usually performed in the seated position. It is advisable to take dated, pretreatment photographs of the patient at rest, frowning, smiling, nose scrunching, puckering, and with the brows raised, both front and side views as needed, for later evaluation of treatment efficacy and duration.

- Cleanse the area to be injected with alcohol and allow it to dry completely.
- 2. Topically applied anesthesia (e.g., Betacaine, TripleCaine, or equivalent) may be used at injection sites. It should be applied at least 30 minutes in advance to be beneficial.
- Apply a cold gel pack or glove with ice or water to the proposed injection site to decrease injection discomfort and to cause vasoconstriction.
- 4. After injection, apply a dry gauze or tissue and ask the patient to hold pressure for a few minutes to reduce bruising and flatten any tissue elevation. Do not let the patient rub the area lest the BTX-A be spread to unwanted areas.
- Injections are most effective and comfortable when made into the subcutaneous tissue rather than into the muscle or periosteum, or intradermally.

### Treatment of Forehead Wrinkles and Frontalis Muscle Contraction Headaches

Horizontal forehead wrinkles and some "stress" or tension headaches are caused by contraction of the frontalis muscle. This muscle usually runs in two bands from the upper margin of the orbits to the scalp. Midforehead creases are usually "sympathy" wrinkles, but this area occasionally requires injection as well. Be aware and careful that inadvertant frontalis contraction may be masking brow ptosis, which would allow excess upper lid skin to collapse down toward or

onto the upper lashes. This will be unmasked when Botox or Dysport is administered. Look for this by pushing the forehead down into a fully relaxed/smooth position and see if the patient has or complains of the excess skin on the upper lid.

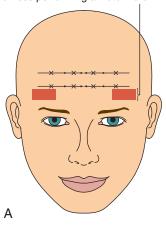

- 1. Take pretreatment photographs of the patient.
- 2. Cleanse the injection sites with alcohol and allow them to dry.
- 3. Have the patient raise the eyebrows to delineate the muscles.
- 4. Inject a total of 20 to 30 U of Botox or 50 to 100 U of Dysport subcutaneously (Fig. 56-3) into the ridges between the wrinkles (furrows) at indicated sites (2.5 to 5 U Botox or 5 to 15 U Dysport per site). Injections can be made relatively perpendicularly to the forehead or threaded under the tissue and injected as the needle is withdrawn. Intramuscular injections tend to bleed more, are less comfortable, and do not provide a better response. Avoid the area between the eyebrows and 1 cm above the superior edge of the orbit lateral to the midpupillary line (or the lowest frontal wrinkle) to decrease the risk of iatrogenic ptosis. Always stay above the lowest line. Eyebrow or upper lid ptosis can last weeks before fading. For treatment of lid ptosis, see the section on Complications.

### Treatment of Glabellar Wrinkles (Frown Lines)

Frown lines are caused by the contraction of several muscles; the corrugator runs diagonally from the skin of the medial brow to the bony bridge (root) of the nose. The procerus is a Y-shaped muscle that runs up the bridge of the nose to the forehead. The orbicularis oculi courses around the orbit of the eye. The depressor supercilii muscle is between them. It adds to the depression of the medial brow. Have the patient frown and scrunch his or her nose to identify the dynamic wrinkles, and inject a total of 20 to 40 U of Botox into these areas after each site is cleansed with alcohol, thoroughly dried, and chilled. Toxin is injected into each of the five to seven injection sites proportional to the effect desired. The injection sites are as follows (Fig. 56-4):

- Site 1: The bridge of the nose at the level of the lower margin of the upper lid with the eye normally open (5 to 6 U Botox, 10 to 15 U Dysport)
- Sites 2 and 3: Directly above each medial canthus at or above the level of the medial orbital bone (4 to 5 U Botox, 10 to 15 U

Avoid injections from 1 cm above down to the superior orbital rim, and lateral to the midpupillary line, unless performing a Botox "brow lift"

**Figure 56-3 A,** Treatment of frontalis muscle (forehead wrinkles). See text for details. **B,** Before. **C,** After.

Dysport; injecting below the edge of the orbit may cause lid ptosis)

- Sites 4 and 5: About 1 cm above and slightly lateral to sites 2 and 3 following the direction of the corrugator on each side (4 to 5 U Botox, 10 to 15 U Dysport)
- Sites 6 and 7: About 1 cm above the brow at each midpupillary line, if necessary (4 to 5 U Botox, 10 to 15 U Dysport; see Fig. 56-4)

Variations in muscular anatomy should be appreciated and treated accordingly in terms of dose and injection location. Do not inject below the superior edge of the orbit, even if the patient has preexisting brow ptosis; this can result in worsening brow ptosis and new upper lid ptosis.

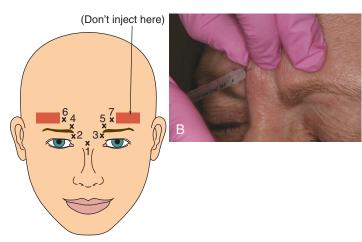

# Treatment of Lateral Orbital Wrinkles (Crow's Feet)

Lateral orbital creases are created by contraction of the orbicularis oculi and photoaging. Photoaging and lateral brow ptosis cause static wrinkles, which may not be removed by BTX-A injections

alone. Therefore, in older patients who have significant photoaging, the objective of treatment is to minimize rather than abolish the wrinkles entirely. A total of 9 to 15 U of Botox or equivalent dose of Dysport (1 U Botox to 2.5 to 4 U Dysport) is injected in a fanlike pattern into two to five sites on each side, 1 cm lateral to the edge of the orbit (Fig. 56-5). Occasionally, anatomy dictates a second row of injections be placed farther out from the lateral canthus to control a wider orbicularis oculi. Injections made too close to the lower lid margin may cause temporary lower eyelid droop or scleral show, or may worsen infraorbital festoons. Laser treatments and conservative filler injections to the static wrinkles complement the use of Botox in this area. If there are hypertrophic orbicularis oculi muscle folds under the eye with smiling or unapposed, dynamic, inferior orbicularis wrinkles are present, an additional 2 to 4 U of Botox or an equivalent dose of Dysport may be injected subcutaneously at the level of the lower lid crease. Reevaluate results in 2 weeks and retreat as needed.

Insert the needle from a lateral approach to make a smooth entrance into the subcutaneous tissue. Brace or rest your hand(s) on the patient to have the best control over the needle tip and plunger. Start superiorly and inject 2 to 3 U of Botox into each furrow (two to five wrinkles), following the shape of the lateral orbital margin.

**Figure 56-4 A,** Treatment of frown lines (glabellar muscle). Direct the needle into the bulk of the contracted muscle for corrugator, procerus, and lip injections. All others are directed subcutaneously. See text for details. **B,** Injecting botulinum toxin into the glabellar area for frown lines.

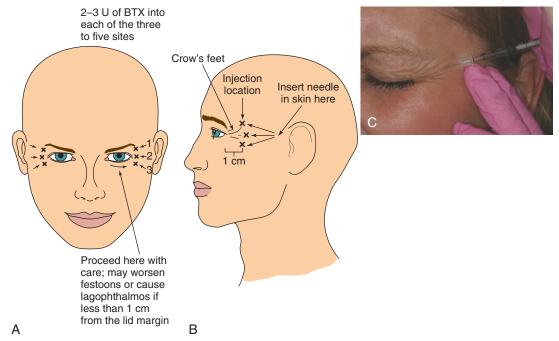

Figure 56-5 Treatment of lateral orbital wrinkles (crow's feet). In this case, three crow's feet wrinkles are treated with three injections. **A,** Frontal view. **B,** Lateral view. **C,** Injecting botulinum toxin for rhytids of the lateral canthal area (crow's feet).

### Botox "Brow Lift" and Shaping the Brow

The Botox "brow lift" (Fig. 56-6) relaxes the lateral brow depressors (orbicularis oculi) and medial aspect of the corrugator so that the action of the frontalis muscle is unopposed. To lift the lateral brow, inject 3 to 5 U of Botox at or above the lateral orbit into the brow where you feel the suture line between the frontal and temporal bones on each side. Then inject 3 to 5 U into the corrugator above the medial canthus on each side if the medial brow needs elevation as well. Do not inject the frontalis above these areas, or little lift will be achieved. If there is too much elevation of the medial brow (sad look) or lateral brow ("Spock eyed"), the frontalis muscle may be conservatively injected with a unit or two of Botox at a time until reasonable brow shape and symmetry are restored.

### **Treatment of Perioral Lines**

Contraction of the orbicularis oris can cause vertical lines through and above the vermilion margin, which worsen with smoking and photoaging. Careful injection of 1 to 2 U of Botox into the *valley*  of the wrinkle at one or two sites per side into the orbicularis oris muscle helps alleviate contraction (Fig. 56-7). This helps decrease a "gummy smile" in select patients, but they must be warned about the risk of temporary lip droop, which leads to drooling, or lessened or asymmetric smiles. If the "gummy smile" persists, 3 to 5 U of Botox can be injected into the levator labii superioris muscle (see Fig. 56-2 for a depiction of the muscle) in the area of the canine fossa bilaterally. Subtle relaxation of orbicularis allows for an increase in vertical height of the lip (outward pout) by everting the dry vermilion.

After these very precise injections, have the patient avoid rubbing the injection sites to decrease the risk of migration of the toxin to adjacent muscles.

### **Treatment of Depressed Commissures**

Inject 3 to 5 U of Botox along the margin of the jaw directly below each corner of the mouth into the depressor anguli oris muscle (see Fig. 56-2), just anterior to the masseter muscle, which can be

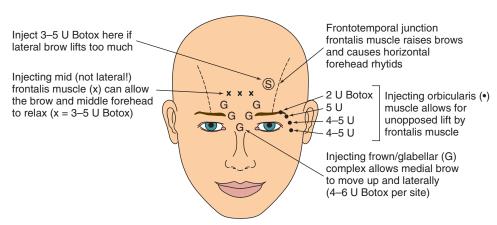

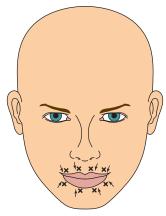

Figure 56-6 Brow lift injection sites.

**Figure 56-7** Treatment of perioral lines. Inject up to 2 U of botulinum toxin into each valley caused by orbicularis oris contraction.

palpated at the level of the mandible when the patient grits his or her teeth. Check results in 2 weeks. Reinforce with further injections if needed.

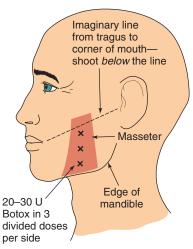

# Treatment of Wrinkled ("Walnut") or Elevated Chin

Inject 5 to 10 U of Botox centrally into the lower part of the chin (mentalis muscle; see Fig. 56-2) or 5 U/side to a clefted chin. Too high an injection in this area can cause lower lip droop. Check results in 2 weeks. Reinforce with further Botox as needed.

# Treatment of Hypertrophic Masseter Muscles

Some (usually female) patients have an angular/squared-off jawline that appears bulky and masculine. Reducing the bulk of the lower half of the masseter muscle helps soften and round that area to obtain a more feminine/oval shape to the face or balance the "pear" shape that patients demonstrate with age. This treatment is more requested by patients of Asian descent. It is also useful for helping to treat patients who chronically grind their teeth or have temporomandibular joint dysfunction.

Draw an imaginary line between the tragus and the corner of the mouth. Inject 20 to 30 U of Botox per side, in three divided doses, below the level of the line, down to the level of the mandible, into the bulk of the masseter muscle (Fig. 56-8). This preserves upper

**Figure 56-8** Treatment of hypertrophic masseter muscles to narrow lower face.

cheek volume while the lower face subjectively thins (masseter muscle atrophies from lack of use) after several months, and can be maintained indefinitely.

#### **Treatment of Neck Bands**

Botox is more effective on vertical platysmal bands than horizontal bands. Grasp each band where it is most prominent and inject 2 to 5 U of Botox or equivalent dose of Dysport *subcutaneously*, every 1 to 2 cm, and re-evaluate in 2 weeks. Avoid accidently treating the strap muscles or making deep injections that could cause dysphonia, dysphagia, and neck weakness.

# Treatment of Primary Hyperhidrosis

Excessive sweat production of the hands and armpits are common conditions that are often treated with topical applications of aluminum salts, iontophoresis, and local and systemic anticholinergic medications. When such treatments fail or give unacceptable side effects, studies have shown that Botox injections may inhibit sweating for 1 to frequently up to 8 months without muscle weakness or other side effects. A 100-U vial of Botox is diluted with 1 to 2 mL of sterile saline, yielding an effective dose of 10 or 5 U per 0.1 mL, respectively. A starch iodine test may be performed to evaluate the major area(s) of hyperhidrosis by thinly applying a liquid iodine solution to the affected areas, allowing it to dry, and then dusting the areas with corn starch. The affected areas will turn blue and can be injected. However, most patients will be able to identify where the area of sweating is most prominent. Roughly 20 small, 2.5-U, subcutaneous blebs are injected, spaced every 1 to 2 cm, into an affected axilla or palm. Topical anesthetics, ice, or continual cold air anesthesia make these injections tolerable. Patients may note some increase in apparent sweat production in surrounding untreated areas and need further treatment.

# SAMPLE OPERATIVE REPORT AND PROGRESS NOTE

See Figure 56-1. The following is a sample SOAP (Subjective, Objective, Assessment, Plan) note for Botox treatment of crow's feet:

- S—48-year-old woman with no medical problems or contraindications requests Botox chemodenervation of orbicularis oculi muscles to decrease the appearance of dynamic crow's feet.
- O—After informed consent and preoperative pictures were obtained, the patient was positioned sitting upright with head supported. Topical anesthetic was applied for 30 minutes and topical ice momentarily applied before 3 injections of 3-plus units of fresh Botox were injected subcutaneously via 30-gauge needle about a centimeter lateral to the lateral orbit on each side. Topical compression was applied to each site. There was no bruising. The injections were tolerated well.

Botox lot no.:\_\_\_\_\_ Expiration date:\_\_\_\_\_ Mix date:

A—Botox Chemodenervation of Orbicularis Oculi Muscles; Bilateral; 20 U

P—Patient discharged in stable condition with written instructions. Recheck in 2 weeks or as necessary.

#### **DYSPORT USE VERSUS BOTOX USE**

Dysport is currently a bit less expensive to effectively treat an area for a similar duration of action as Botox. Dysport is not a household name in the United States, but it has been safely used elsewhere for over 2 decades. The onset of action of Dysport appears to be slightly sooner than that of Botox. The injection techniques are similar once it is understood that 1 U of Botox is equivalent to 2.5 to 4 U of Dysport.

The easiest, least risky place to inject is the glabella. Once you have mastered that area, try the lateral eyes and then the forehead and brow shaping. Lower face injections are mastered once you are comfortable and consistent with upper face treatments and bundling BTX-A treatments with fillers, skin treatments, and skin care programs. Symmetric injection is preferable unless you are trying to correct facial asymmetry. Start with lower doses. Increase the dose to increase the effect and duration. If an area does not respond after 2 weeks, try increasing the dose by 30% to 50%. If it still does not work, you may have one of the few patients who do not respond to these treatments. It is better to inject too high above the brow and leave horizontal forehead rhytids than to drop the brow or upper eyelid. BTX-A is a powerful and forgiving tool for performing minimally invasive, temporary facial shaping. Patients who get the best results are usually working with a physician who integrates various modalities to address loss of facial and neck volume and proportion, skin texture, tone, color, clarity, and elasticity.

# **COMPLICATIONS**

- Brow ptosis
- Ptosis of the upper eyelid
- Double vision
- Temporary discomfort
- Headache, nausea, or flulike symptoms
- Swelling
- Bruising
- Lip droop and drooling
- Temporary facial asymmetry
- Abnormal or lack of facial expression
- Dry mouth (reported after Myobloc injections)
- Incomplete or poor results
- Possible unknown long-term effects (e.g., muscle atrophy, nerve irritability, production of antibodies with unknown effects to general health)

There have been no long-term adverse effects or health hazards related to the use of Botox. Little if any allergy or hypersensitivity has been documented. Repetitive doses of greater than 300 U may lead to production of antibodies, making the patient resistant to further treatment with that particular serotype of BTX. However, it is rare that more than 100 U of Botox is used at any one time for cosmetic uses, or greater than 200 U used at one sitting for the treatment of hyperhidrosis.

Ptosis of the upper eyelid is infrequent (1% to 2%). This temporary side effect of Botox injection can be treated with apraclonidine 0.5% (Iopidine; Alcon Laboratories, Fort Worth, Tex) ophthalmic drops (two drops three times daily to affected eyes). Alternatively, a compounding pharmacy can dilute Neo-Synephrine (phenylephrine) 2.5% ophthalmic drops to 1.25%. Neo-Synephrine drops give relief of lid ptosis in over 80% of patients for 3 to 4 hours, but may cause pupillary dilation with associated photophobia and difficulty with near vision temporarily.

Some patients find injections uncomfortable, which can be minimized by the use of topical anesthetic, ice before injection, small-gauge needles, subcutaneous injections, and topical and verbal distraction during injections. Chilling the tissue to be injected briefly with cold air or direct-contact chilling (e.g., devices available from Zimmer MedizinSystems [www.zimmerusa.com] and ThermoTek [www.thermotekusa.com]) can improve comfort and decrease bruising as well. The risk of bruising and swelling at injection sites is minimized by preinjection chilling and postinjection direct pressure, as described previously. Aspirin and other antiplatelet medications should be avoided for 2 weeks before treatment if possible. Keep injection volumes low. Do not inject below or less than 1 cm above the superior orbital margin lateral to the midpupillary line to prevent brow and upper lid ptosis.

# **POSTPROCEDURE PATIENT EDUCATION**

It is important that the patient understands that Botox injections may not entirely alleviate all dynamic wrinkles every time and that the results of the treatment are temporary. Most patients achieve a 60% to 90% improvement 3 to 14 days after their injections. Recheck the patient in about 2 weeks. Review the preinjection photographs, and reinject the areas that have not responded satisfactorily. Remind patients that the objective of treatment is improvement, not perfection, and that some movement is preferred over a frozen face.

It is best if the patient does not lie down or participate in vigorous exercise for at least 4 hours after the injection. Exercising the facial muscles injected by raising the eyebrows, furrowing the brows, and frowning deeply 10 times every 15 minutes for 4 hours will enhance the binding effect of BTX-A.

#### **CONCLUSION**

Botulinum toxin has been used safely in humans since the early 1980s. The FDA approved Botox for cosmetic use in 2002. Botox has been demonstrated to be a safe and effective therapy in a number of studies. It is well accepted in the medical community as a valuable adjunct for the treatment of dynamic wrinkles of the face and neck, control of muscle contraction and vascular headaches, and treatment of hyperhidrosis. The effects of the injections generally last from 3 to 5 months and then fade gradually, with the exception of hyperhidrosis, where they are more likely to be effective for 7 to 9 months.

#### **PATIENT EDUCATION GUIDES**

See the patient education preinjection and postinjection information and patient consent forms online at www.expertconsult.com.

# **CPT/BILLING CODES**

Note that for cosmetic purposes, there are no CPT codes nor is there insurance coverage. Insurances vary in their coverage for any Botox injection and it is best to have the patient clarify this with his or her carrier before doing any injections. The fees are often in the thousands of dollars and patients need to be aware of their financial responsibilities.

- 64612 Chemodenervation of muscle(s); muscles innervated by facial nerve (e.g., blepharospasm, hemifacial spasm). Use for migraines, tension headaches
- 64613 Neck muscles (e.g., spasmodic torticollis)
- 64614 Extremity or trunk (e.g., dystonia, cerebral palsy)
- 64650 Chemodenervation of eccrine glands; both axillae
- 64653 Chemodenervation of other areas (e.g., scalp, face, neck)
- 64999 For hands or feet (unlisted procedure, nervous system)

# **ICD-9-CM DIAGNOSTIC CODES**

The cost of Botox is about \$5.25 per unit (100-U vial) in 2009 and under \$1.50 per unit for Dysport. Charges for injections range from \$8 to \$15 per Botox unit, depending on additional overhead, amount used, and prevailing charges in the area.

- 307.81 Headache: tension
- 333.81 Blepharospasm
- 346.9 Headache: migraine
- 70521 Hyperhidrosis: face, soles, axilla

# **J** Codes

J0585 Botulinum Toxin A per unit (e.g., Botox)

J0587 Botulinum Toxin B per 100 units (e.g., Myobloc)

# TISSUE FILLER

Mel Elson

Soft tissue augmentation has been performed since the 15th century, when physicians transplanted fat en bloc to correct defects, usually facial disfigurements related to wartime injuries. The modern era began in 1981, when the U.S. Food and Drug Administration (FDA) approved Zyderm I, a suspension of 3.5% bovine collagen with 0.3% lidocaine. Although not particularly long lasting or effective for a great deal of indications, it was sufficient to treat acne scars and fine lines and wrinkles, such as nasolabial folds, oral commissures, and crow's feet.

Over the past 25 years, products and techniques have evolved so that there are now about 300 different filling materials. Table 57-1 lists the most common filling materials used around the world. Modern techniques and products are used not only for the classic indications for soft tissue augmentation, but also to rebuild and renew faces by replacing lost tissue volume so that they appear much younger.

### **INDICATIONS**

The indications for soft tissue augmentation have evolved over the years. Although they remain in the realm of cosmetic treatment, some, such as the soft-tissue injectables for human immunodeficiency virus (HIV) lipoatrophy, are life-changing. The areas of treatment have also expanded from the injection of nasolabial folds (Fig. 57-1), oral commissures, crow's feet, and glabella to neck lines, hands, cheeks (Fig. 57-2), bridge of the nose, chin (Fig. 57-3), and any area of atrophy.

#### **CONTRAINDICATIONS**

There are both absolute and relative contraindications, as well as those that are generally applicable to all fillers and those that are specific to certain fillers.

- Allergies: Although there is still some limited use of bovine material, it is limited to Zyderm and Zyplast (Inamed, Santa Barbara, Calif) and Artefill (currently off the market). Any allergy to bovine protein precludes the use of these materials, and skin testing must take place before use. Animal sources are rarely used for fillers any longer, although there are exceptions. There is one hyaluronic acid product from avian sources (cock's comb); however, this does not require skin testing. Most materials are based on hyaluronic acid, which will be discussed in detail and which does not elicit a delayed hypersensitivity response. In addition, only rarely do these materials contain lidocaine, so allergy is not a substantive problem.
- Active infection: Any active infection or skin disease in the area to be injected is a contraindication.
- Location: Injection of robust substances such as Zyplast, Cosmoplast, and biphasic fillers into the glabellar complex must be avoided.
- Patients who are pregnant or breast-feeding should not undergo augmentation.

Relative contraindications include the following:

- Unrealistic expectations.
- Body dysmorphic disorder or patients seeking a psychological boost after a life-changing event such as a divorce, death of a family member, or loss of a job. Patients should wait and let things settle down before rushing into a procedure that may or may not be right for them and will not solve the emotional issue.
- Use of anticoagulants. Preparation for the injections to prevent bruising, particularly when using biphasic fillers, should consist of discontinuing aspirin and vitamin E for at least 72 hours, and if the patient is on warfarin to consult with the patient's primary care physician regarding the feasibility of discontinuing the drug for a few days. If this cannot be done, the patient should not be injected with biphasic fillers and extreme caution must be taken even with hyaluronic acid fillers. Topical vitamin K cream twice a day for a week before and after will significantly decrease the bruising.

# INITIAL EXAMINATION AND PATIENT PREPARATION

A complete history and physical examination should be performed before soft tissue augmentation, and particular emphasis should be placed on any prior injections or Botox treatments, what the patient is using for skin care, and any allergic reactions or difficulties with any cosmetic procedures in the past.

Obtaining good-quality photographs before injection is strongly encouraged in all patients.

Informed consent should include all the pertinent information regarding possible side effects, cost, and alternative treatments, as well as a statement at the end that the patient has been asked if he or she has any further concerns or questions and stated that he or she does not. It is also prudent, if at all possible, to schedule another session for the patient 2 to 3 weeks after treatment to see if what both the patient and the physician desired has been accomplished. Do not call this a session "for a possible touch-up," but one for injection in case it is needed. When possible, always try to schedule two injection sessions so that if there are any issues they can be easily resolved. The problem with calling a second injection a "touch-up" is that often the patient feels that there was something done incorrectly with the first injection and will be hesitant to pay for a "touch-up."

# **EQUIPMENT FOR SOFT TISSUE AUGMENTATION**

- Injectable material of choice
- Appropriate-gauge needles for the material of choice
- Anesthetic material
- Ice
- Topical vitamin K
- Alcohol swabs for skin preparation

TABLE 57-1 Mos	TABLE 57-1 Most Common Filling Materials Worldwide

EMA, ethyl methacrylate; EU, European Union; HA, hyaluronic acid; HEMA, hydroxyethyl methacrylate; NASHA, stabilized nonanimal hyaluronic acid; PMMA, polymethyl methacrylate.

\*The CE, or European Conformity, mark indicates the product has met EU consumer safety, health, or environmental requirements. It applies to all countries of the EU, as well as the four countries of the European Free Trade Area (Iceland, Liechtenstein, Norway, and Switzerland) and Turkey.

### **Material for Injection**

This is the point where things become very complicated because there are a myriad of materials available for use. It is not possible to obtain expertise or even experience with all filling materials that are currently available; however, familiarity with a few will provide an armamentarium that will be sufficient for most needs (Table 57-2).

### **Collagen Products from Human Fibroblasts**

CosmoDerm has for the most part replaced Zyderm because it is the same material with the same indications, but with the collagen derived from human foreskin fibroblasts. Therefore it does not require allergy skin testing. CosmoPlast is the same as Zyplast except that it is also derived from human tissue.

Figure 57-1 Radiesse injection of the nasolabial folds. Before (A) and 3 (B), 6 (C), and 12 (D) months after treatment. Volume injected (in milliliters): baseline, 4; 1 month, 0; 6 months, 2; total, 6.

# Collagen Products from Bacterial Hyaluronic Acid

Most of the materials available now are based on hyaluronic acid. Hyaluronic acid products have become very popular around the world, and there are indeed many of them, but the most significant in this category are the products from Qmed in Sweden (Restylane, and Perlane Restylane fine lines) and those from Inamed-Allergan (Juvéderm Ultra, Juvéderm Ultra Plus, and Juvéderm Fine Line—also known as Juvéderm 24, Juvéderm 30, and Juvéderm 18). All of these products are manufactured by bacterial fermentation in the laboratory, after which the hyaluronic acid undergoes various

degrees of cross-linking and folding to increase the longevity of the implant. Without any manipulation of the molecule to increase cross-linking and molecular weight, the implant would be very short lived because pure hyaluronic acid lasts only hours to a few days when injected into the skin. There is a product in use in Asia called Hyalan that is actually injected into the skin to act as a moisturizer. Hyaluronic acid traps and attracts water to it. This is also the reason that when hyaluronic acid is injected as filler the end result is a smooth surface—because water is absorbed into the area of injection. Although there is great similarity between the two types of hyaluronic acid fillers available, there is much debate as to which is

Figure 57-2 Radiesse injection of the cheeks. Before (A) and 3 (B), 6 (C), and 12 (D) months after treatments. Volume injected (in milliliters): baseline, 8; 1 month, 5; 6 months, 5.7; total, 18.7.

Figure 57-3 Radiesse injection of the chin. Before (A) and 3 (B) and 12 (C) months after treatments (no 6-month postinjection photograph available). Volume injected (in milliliters): baseline, 6; I month, 0.8; 6 months, 2; total, 8.8.

the longer lasting, which produces smoother results, and which is more comfortable for the patient. The higher–molecular-weight products are used for more aggressive augmentation such as for scars, lip augmentation, and some degree of sculpting. The lower–molecular-weight products are used for fine lines such as crow's feet and lip lines. Midrange products are used for the majority of augmentation needs such as the treatment of nasolabial folds, oral commissures, and the glabellar area.

The most common fillers used in the United States are Restylane and Perlane (Medicis, Scottsdale, Ariz) and Juvéderm Ultra and Juvéderm Ultra Plus (Allergan, Irvine, Calif), although there are some others available.

# Noncollagen, Non-Hyaluronic Acid Products

Some products are not collagen based and do not contain hyaluronic acid—Sculptra (called New-Fill in Europe) and Radiesse are the most widely used at this time. Sculptra (Dermik/Aventis, Bridgewater, NJ) is a polymer of lactic acid that is provided as a powder to be

TABLE 57-2 Common Uses of Major Fillers					
Filler	NLF	ОС	Glabella	Periocular	Lips
,	1.5 mL 1–2 mL	I mL I mL	0.3 mL 0.2 mL	0.1 mL 0.1 mL	I-2 mL I-2 mL
Radiesse	0.8 mL	0.4 mL		_	
Teosyal Revanesse	I mL I mL	0.5 mL 0.5 mL	0.2 mL 0.2 mL	0.1 mL 0.1 mL	1–2 mL 1–2 mL

- For this table, it is assumed that the clinician understands the following:

   Every patient is different and the volumes given are averages only.
- There a number of different fillers in each line designated for certain uses that are not interchangeable (e.g., Restylane is for NLF, Perlane is better for lips).
- Teosyal has seven different products in the line, so each product should be used in the appropriate area.
- Never use a biphasic filler in the lips.
- Never use a robust filler around the eyes or in the area of the glabella.
- The volumes refer to each side of treatment.

NLF, nasolabial folds; OC, oral commissures.

mixed before injection with water or lidocaine. It is very difficult to force into solution, and it is recommended to mix the product the day before use, if possible. It was initially approved in the United States for HIV lipoatrophy and is used in many areas for soft tissue augmentation, including cheek augmentation and postrhinoplasty defects. It induces new collagen formation as the implant itself degrades to lactic acid and is absorbed completely by the body. There has been a report of this material inducing correction lasting 40 months, although probably 12 to 24 months is more likely. It is injected into the lowest part of the dermis at the junction with the subcutaneous tissue using a 26-gauge needle, and does require some degree of anesthesia.

Radiesse (Bioform Medical, San Mateo, Calif) is quickly becoming one of the most popular filling materials in the world because it is a biphasic filler that produces long-lasting results (although not permanent because the second phase is biodegradable). A biphasic filler is one that has two phases. Phase one corrects the defect and triggers the second phase, which induces the patient to form collagen from fibroblast infiltration. The key point is that any biphasic material should be both biocompatible and biodegradable so that eventually the only substance that remains is the patient's own collagen producing the correction. Radiesse consists of 70% acrylic hydrogel with 30% calcium hydroxylapatite beads. Calcium hydroxylapatite has been used as a dental material for more than 20 years. Radiesse has been approved by the FDA for vocal fold augmentation, as a radiographic marker, and for maxillofacial augmentation. More recently, the FDA approved the material for the treatment of HIV lipoatrophy and nasolabial fold augmentation. It is injected at the junction of the dermis and subcutaneous tissue using a 27-gauge needle. When augmenting cheeks or correcting nasolabial folds, it is recommended to use a 27-gauge, 11/4-inch needle rather than the more common  $\frac{1}{2}$ -inch needle, which can be used in shorter areas such as the oral commissures.

The Radiesse injection technique is more specific than with other materials. The needle should be inserted through the dermis (where resistance is felt) and then into the subcutaneous space (where there is little resistance). The material is injected in a retrograde fashion with care taken to discontinue injecting before withdrawal to avoid inadvertent injection into the dermis. Although this is difficult to master, it is imperative that the injections be done in this manner to avoid

foreign body reactions. Rather than a single pass, multiple passes are made.

- To correct the *nasolabial fold*, material is injected under the fold in the manner just described, and then closer to the nose, with still a third linear thread just onto the cheek slightly above the fold. *Caution* should also be taken to make the injections in the linear thread smooth without hesitation during the injection so that lumps do not occur. This technique will form a "scaffold" under the nasolabial fold to elevate it.
- To augment cheeks the same technique is used, but with an additional triple linear thread at right angles to the first set. This would also apply to correction of HIV lipoatrophy, rhinoplasty defect, or any other true augmentation.

Also see later under Plane of Injection, in the Technique section.

The gel and the particles are injected into the desired area of correction. The gel dissipates over a 3- to 4-month period; during this time the particles that have been delivered induce fibroblast collection, stimulating new collagen formation. As the gel disappears, the new collagen remains, producing correction for approximately 18 months or more. The main advantage to Radiesse is that the calcium hydroxylapatite particles are biodegradable and disappear over time, avoiding the possible problems of permanent fillers.

This filler also contains no anesthetic, so it is advisable to *provide some form of anesthesia for the patient*. Augmentation of the nasolabial fold, oral commissures, and the like may require only a topical anesthetic such as Ela-Max or Betacaine, but cheek augmentation or treatment of HIV lipoatrophy usually requires a nerve block. Radiesse should not be used for lip augmentation because significant beading may result.

#### **GENERAL GUIDELINES**

When using materials for soft tissue augmentation, certain guidelines should be kept in mind.

- The shortest-lasting materials (low molecular weight) are the ones that are injected highest in the dermis with the smallest-gauge needle (30, 32, or 33 gauge), may require overcorrection, can be repeated often, and are forgiving if an error occurs. They usually will last 3 to 4 months.
- Mid-molecular-weight materials should be injected with a 30-gauge needle into the mid-dermis and can be expected to last approximately 6 to 12 months.
- The most robust materials (highest molecular weight) are injected deeper into the tissues, use larger needles (26 or 27 gauge), must *never* be overcorrected, cannot be repeated very often (e.g., no more than twice a year), and may be totally unforgiving in the event of an error on the part of the injector. Inexperienced injectors should begin with more forgiving materials such as Cosmo-Derm, Restylane, and Juvéderm Ultra and should receive one-on-one instruction from an experienced injector to obtain proper knowledge of soft tissue augmentation.

# PREPROCEDURE PATIENT PREPARATION

Once a history, physical examination, photographs, and informed consent are obtained, the areas to be injected should be cleansed with alcohol. The patient should not be wearing makeup. Ice can be applied both before and after the procedure for patient comfort. If more anesthesia is desired or required, a field block, nerve block, or mixing the filler material with 0.2 mL of 2% lidocaine with epinephrine will provide more patient comfort.

# **TECHNIQUE**

The patient should be in the *upright position* for injection. Technique depends on what the goal is for each individual patient. Provide

traction by pulling the skin in the direction of the defect and aligning the needle with the defect to be injected. Use the smallest-gauge needle possible (usually provided by the manufacturer with the material). The plane of injection and degree of correction are critical to achieve complete, smooth, and long-lasting correction of the defect.

# **Basic Technique**

Whenever a dermal filler is being injected, regardless of the material being used, the level of injection, or the defect being corrected, the *key technical concept is to inject smoothly.* One should consider the material flowing through the needle, but the syringe–needle unit should be looked on as a continuation of the injector's hand and arm. The action should be smooth, like laying down icing on a cake. Once movement begins, do not stop until the end point is reached.

# Plane of Injection

Collagen should be injected into the superficial dermis with some overcorrection. All hyaluronic acid products should be injected into the dermis with just slight undercorrection because water will come into the area immediately and continue to do so over time, enhancing the correction. All biphasic (e.g., Artefill and Radiesse) and robust (e.g., Sculptra) fillers must be placed at the dermal–subcutaneous junction with no overcorrection and care taken to avoid placing any material in the dermis.

When injecting biphasic materials, a fanlike scaffold, also known as the fern technique, should be formed under the defect to hold up the defect (see the earlier discussion in the section on Noncollagen, Non–Hyaluronic Acid Products). This is performed by entering the subcutaneous space (as soon as resistance gives, one has entered that space) and injecting in the same plane but at varying angles, and not exiting through the dermis before discontinuing the injection so that no material is deposited into the dermis, thus avoiding a possible granulomatous response.

# COMMON ERRORS IN SOFT TISSUE AUGMENTATION

- Overcorrecting in areas of fine lines (e.g., periorbital and perioral)
- Injecting biphasic fillers into the dermis
- Injecting too robust a filler into the glabellar complex
- Not providing sufficient anesthesia to make the patient comfortable
- Not following up with a second patient visit
- Not taking before and after photographs
- Not obtaining informed consent
- Not taking a complete medical history before injection
- Using a permanent filler of any type
- Not asking patients which type of filler they had injected by a former physician

# **COMPLICATIONS**

- Bruising: Some degree of bruising is the most common complication. It can be eliminated or decreased with the application of ice and topical vitamin K before and after the injection session. (See the earlier discussion of relative contraindications.)
- Erythema: This is common after injection of any material and is easily addressed with topical vitamin K and ice.
- Edema: This is not unusual and is particularly common with hyaluronic acid products; it is temporary and of no consequence.
- Infection: Although infection is theoretically possible with dermal fillers, I have never seen this occur in over 25 years of practice.
- Skin necrosis: This can occur anywhere on the face from injection of any material; however, the most common area of occurrence

is the glabellar complex owing to the paucity of collateral circulation in this area. The necrosis is not due to injection into a vessel but to the material crimping a vessel in this area, thus occluding the blood supply. If there is sudden blanching and the patient states the injection has become painful, stop immediately and apply nitroglycerin paste or dimethyl sulfoxide (DMSO) to increase the circulation in the area.

 Uneven results: The possibility of this occurrence is the primary reason to schedule a second injection session 2 weeks after the first. This is also one of the primary reasons to take pretreatment photographs on every patient; we are not symmetric to begin with, and some patients do not realize that.

# POSTPROCEDURE PATIENT CARE AND EDUCATION

- Apply ice immediately after injection.
- Apply topical vitamin K twice daily for at least 5 days.
- No warfarin, aspirin, or vitamin E for 48 hours.
- No significant sun exposure for 48 hours.

Patient should be advised to do the following for overall skin health:

- Apply SPF 30 sunscreen every morning (A and B block).
- · Apply retinoids each evening,
- Do not smoke.
- Avoid tanning beds completely.
- Return for another injection session in 2 weeks and then whenever desired in the future, but before all the correction has subsided.

#### **PEARLS**

- Use the smallest-gauge needle through which the material can flow.
- Use ice before and during the injection session for more patient comfort.
- When injecting the lips, move slightly onto the lip (about 1 mm) to achieve longer-lasting correction.
- To avoid lumpy results, make sure your movements are smooth.
- Try using a 32- or 33-gauge needle for fine lines.
- Change needles before the syringe is empty because the skin dulls needles.
- Always underestimate how long correction will last—in other words, underpromise and overdeliver.
- Do not attempt to learn technique except from an expert (oneon-one, if possible).
- Never talk patients into procedures they are not certain they really want.
- If you are not sure, then don't do it.

# MICRODERMABRASION AND DERMALINFUSION

Basil M. Hantash • Sandy T. Liu

# MICRODERMABRASION: BACKGROUND

The concept of smoothing the skin by removing or abrading the upper layers can be dated as far back as 1500 BC, when Egyptian physicians used a type of "sandpaper" to treat scars. Modern dermabrasion was developed in Germany in the early 1900s by Kromayer, who used human-powered rotating wheels and rasps as a means of removing the epidermis and superficial portions of the dermis. This new technology was mainly used to treat scars, hyperpigmentation, and keratoses; however, acceptance was not forthcoming. It was not until Kurtin, Burks, and others began using motorized wire brushes in the early to mid-1950s that the power of the technology began to be realized. In spite of the great benefits possible with dermabrasion, there are many potential negatives; need for anesthesia, scarring, prolonged downtime, wound care, infection, and contaminated operative field with aerosolized particles that endanger the practitioner and staff. Many of these problems are also encountered with other techniques, such as laser resurfacing and deep chemical peels. These factors, as well as economic considerations, have pushed for development of a new technology that is less debilitating, safer, and more affordable: microdermabrasion (MDA).

MDA was developed in Italy in 1985 and introduced to the American market during the mid-1990s. MDA has spread at an explosive rate. According to data from the American Society for Aesthetic Plastic Surgery, an estimated 557,131 MDA procedures were performed in the United States in 2008. The aim of this chapter is to help the reader better understand MDA's mechanism of action, clinical indications, contraindications, patient selection and initial evaluation criteria, procedure methods, and complications encountered following treatment.

# **MECHANISM OF ACTION**

The most superficial layer of the skin is the stratum corneum, which is a lifeless accumulation of protein and lipid material derived from flattened, dead keratinocytes that forms a barrier to protect the skin from a myriad of invasive insults. From the time a keratinocyte is formed in younger skin, it takes approximately 28 days to mature, die, and flake off the skin surface as dander. As humans age, keratinocyte transit times dramatically increase, trapping pigment and debris in the superficial epidermal layers to give the characteristic stained appearance of aging or solar (actinic) damage. Another skin cell of major importance is the dermal fibroblast, which lies within the dermis and synthesizes extracellular matrix (ECM) components, including proteoglycans (e.g., dermatan sulfate), glycosaminoglycans (e.g., hyaluronic acid), collagen, and elastin. This function decreases with aging and actinic damage. The process of MDA addresses both the stained, debris-laden epidermis and the sluggish fibroblast production of ECM, especially collagen.

# **Epidermal Effects of Microdermabrasion**

The micrographs in Figure 58-1 exhibit the immediate sequential thinning and smoothing of epidermal structures as a result of the abrasive effect of the aluminum oxide crystals moving rapidly across the skin surface. The gentle planing of the upper layers of the skin removes pigmentary impurities and debris held within the stratum corneum and yields a smoother, softer skin surface. Each pass of the MDA handpiece is estimated to ablate approximately 15  $\mu m$  of skin, roughly equal to one pass of the erbium laser. In addition to the immediate smoothing of the skin, the abrasive process seems to stimulate keratinocyte turnover over the long-term. Larson and Shehadi and colleagues have shown increases in epidermal thickness in porcine skin by 9% with MDA.

#### **Dermal Effects of Microdermabrasion**

Most MDA machines are quite simple in principle, having a crystal reservoir that supplies abrasive crystals through a flexible tube to a handpiece that is moved across the skin by the operator. The skin is "tented up" by the negative pressure generated in the machine, and abrasive crystals, usually aluminum oxide (corundum), are simultaneously blown and "sucked" across the skin to remove the upper layers of the epidermis. This can be compared with a fine "sandblasting" technique. Other types of particulate materials are occasionally used for the abrasion process, such as sodium chloride crystals, sodium bicarbonate (baking soda), and magnesium oxide crystals. However, aluminum oxide seems ideal because it is widely available, inert, very hard, has multiple sharp edges, does not readily absorb liquid, and is nontoxic even if inadvertently inhaled. Used crystals and cutaneous debris are removed through suction and collected in a separate waste container, thus creating a closed-loop system that avoids the airborne contaminants of open dermabrasion. The handpieces usually can be fitted with reusable metal tips or disposable plastic tips. The metal tips must be sterilized before use with different patients.

Treatments are superficial enough that they do not cause bleeding or "serum ooze." Some patients with very sensitive skin may experience slight discomfort, but treatments are certainly not painful and are generally well tolerated. No topical anesthetics are needed. After each pass, the bulk of crystals should be removed before continuing. The *second pass* should be at right angles, or perpendicular, to the direction of the first pass. An optional *third pass* is performed with a swirling or circular motion, making sure that the skin is taut and the handpiece tip is moving and not stationary over a single skin point. Skilled operators also pay close attention to the direction of lymphatic flow, especially in areas such as the face, in order not to obstruct drainage and prevent unnecessary edema.

Skin changes are cumulative and treatment sessions are recommended at 7- to 14-day intervals. Depending on the type and

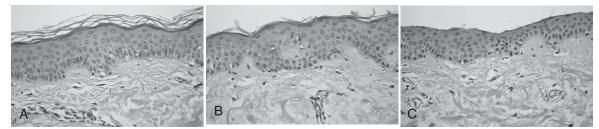

Figure 58-I A, Pretreatment photomicrograph of human skin of the upper back showing fully intact stratum corneum and stratum granulosum. B, Upper back skin on same patient after two passes. Note that the stratum corneum has been markedly ablated. C, Upper back skin after four passes, same region of the back as (A) and (B), but separated by 20 minutes, exhibiting total removal of the stratum corneum and most of the stratum granulosum. (Courtesy of Rick Wilson, MD, Dallas, Tex.)

severity of the skin problem(s), usually between 4 and 15 treatments are offered on an as-needed basis between 1 and 4 months. The patient is usually able to return to most normal activities immediately, unless the skin is extremely sensitive. Mild erythema may be observed, and usually resolves within 12 to 24 hours after treatment.

The operator has great flexibility in treating patients and improving outcomes by varying the depth of penetration to match each patient's unique circumstances and requirements. This is accomplished by controlling the following four factors:

- 1. Density of crystal flow
- 2. Number of passes completed by the operator
- 3. Vacuum pressure
- 4. Handpiece speed over the skin surface

In rare instances (e.g., acne scarring), high vacuum settings (≥20 mm Hg) may be required. The operator should expect variability in vacuum settings and crystal flow with different machines.

#### **INDICATIONS**

Clinical indications for MDA include the following skin conditions:

- Minor acne scarring
- Postoperative/traumatic scarring
- Fine lines and wrinkles
- Superficial pigmentation such as lentigines and ephelides
- Melasma and other disorders of pigmentation
- Postinflammatory hyperpigmentation (PIH) due to acne or eczema, among other causes
- Blending postlaser hyperpigmentation
- Skin texture irregularities
- Actinic keratoses
- Enlarged pores
- Clogged pores and blackheads
- Whiteheads
- Some mild forms of acne
- Keratosis pilaris
- Rosacea (using dermalinfusion; see later discussion)
- Striae distensae

Patients with stage I, II, or III *acne* have done well when MDA is combined with topical retinoid therapy (Fig. 58-2). In this instance, MDA's action on the stratum corneum allows for better absorption of topical medications. Although MDA does not entirely eliminate stretch marks, it can be an effective treatment option when combined with topical therapies. In a study by Abdel-Latif and Elbendary (2008), better results were seen when treating striae rubra than for striae alba, suggesting that treatment may be limited to more recent-onset stretch marks. Moreover, molecular studies showed that type I collagen expression was upregulated in the skin of patients with striae post-MDA treatment. This provides a biologic mechanism for the clinical benefits of MDA treatment in patients with striae rubra. More recently, cosmeceutical agents such as vitamin C have been proposed as therapies for striae. In addition,

work by Lee and colleagues (2003) demonstrated that treatment of ex vivo skin with MDA can significantly increase the uptake of vitamin C. It will be interesting to see whether the combination of MDA and topical vitamin C results in improved clinical outcomes for striae treatment.

#### **DERMALINFUSION**

# **Background**

Dermalinfusion is an innovative procedure that uses MDA technology to increase delivery of active ingredients to treat specific skin conditions such as hyperpigmentation, telangiectasia, papulopustular acne, eczema, photodamage, dehydration, rosacea, and fine lines. It is unique in that it uses a closed-loop vacuum system with a recessed diamond tip rather than microcrystals to exfoliate the skin while simultaneously infusing the topical dermaceutical into the deeper dermal layers. The size, coarseness of the diamond tip, vacuum, and flow rates can all be adjusted depending on the patient's treatment. A major advantage of dermalinfusion is minimal posttreatment erythema and decreased risk of PIH compared with the harsh and abrasive standard MDA treatments. Furthermore, dermalinfusion is ideal for treatment of the lips, papulopustular acne, as well as rosacea, which are all relatively contraindicated with crystalbased MDA. The optimal treatment regimen involves four to six treatments every 1 to 2 weeks and monthly treatments thereafter.

In an unpublished histologic study conducted by Moy (www. plasticsurgerypractice.com/issues/articles/2007-01\_06.asp), patients were pretreated with dermalinfusion in the preauricular area 1 to 3 days before undergoing an elective facelift. During the procedure, the marked dermalinfusion-treated area was removed, fixed with formalin, processed, and then analyzed. The author found that the dermalinfusion treatment created a smooth and uniform abraded

**Figure 58-2 A,** Patient with stage II acne on chronic daily topical retinoids. **B,** Same patient after six SilkPeel treatments combined with dermalinfusion of an antiacne solution.

surface confined to the granular layer approximately 30 to 35  $\mu m$  deep. The epidermal layer, and the keratinosomes in it that help create the hydrophobic barrier, remained intact after treatment. Moreover, addition of a hydrating serum to the abrasive surface showed vacuolization of keratinocytes, displacement of the nucleus, and edema around collagen fibers near the upper papillary dermis. Furthermore, epidermal thickness was increased by 70% after dermalinfusion, consistent with effective absorption and penetration into the papillary dermis. These findings are consistent with rapid hydration of the underlying dermis and help explain the mechanism for the observed clinical improvement in fine wrinkles after MDA plus dermalinfusion treatment.

#### Rosacea Treatment

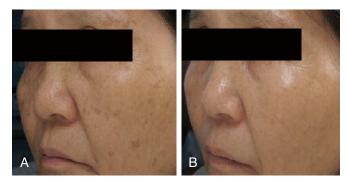

Current treatments of rosacea include avoiding triggers such as sunlight exposure, administration of topical and oral antibiotics, and use of laser and light therapies. Treatment usually lasts 3 to 6 months and is associated with side effects such as skin irritation and dryness, erythema, bruising, and photosensitivity. Moreover, MDA is not recommended for patients with rosacea because it can further aggravate the skin, causing angiogenesis, inflammation, and reactive oxygen species. Dermalinfusion, however, will not exacerbate the deeper epidermal layers and can be considered an alternative monotherapy for patients with rosacea. In a recent study by Desai and colleagues (2006), 30 patients with erythematotelangiectatic or papulopustular rosacea underwent MDA plus dermalinfusion treatment twice a month for a total of 12 weeks. The authors chose to use 2% erythromycin and 2% salicylic acid as their infusion solution to decrease inflammation and induce exfoliation, respectively. Twenty patients completed the entire study: 6 patients with erythematotelangiectatic rosacea and 14 patients with papulopustular rosacea. There was a statistically significant reduction in erythema. papules, and pustules in all patients by the 12th week, with a reduction noted as early as week 4. The authors reported a 42% improvement in erythema in the erythematotelangiectatic group and a 69% decrease in papules and 55% decrease in pustules in the papulopustular group. In addition, photographs taken throughout the study documented an overall improvement in the patients' condition, and there was positive patient feedback regarding tolerability, satisfaction, and overall quality of life. The adverse event most commonly reported by the study participants was transient erythema, which resolved in 3 to 6 hours.

# **Tattoo Treatment**

An interesting case report by Wray and colleagues (2005) documents the first successful treatment of traumatic tattoo with SilkPeel (Envy Medical, Inc., Westlake Village, Calif) MDA treatment during isotretinoin (Accutane) therapy. The adolescent male patient had suffered a traumatic tattoo around the upper and lower eyelids after an explosive accident. The first treatment was performed 48 hours after the accident, with two other treatments on days 3 and 12 postaccident. In addition, comedonal extractors and Vigilon were used as adjunctive therapy for greater efficacy. After the first treatment, more than half of the tattoo marks disappeared, with further improvement reported with each ensuing treatment. The patient was extremely satisfied with the cosmetic outcome, and no complications were reported.

#### Hyperpigmentation Treatment

More recently, Envy Medical (formerly Emed, Inc.), the manufacturer of the SilkPeel MDA system, has introduced a novel approach for the treatment of hyperpigmentation that involves four MDA treatments spaced 1 week apart, in combination with infusion of a novel skin-lightening solution (Lumixyl) developed by the same company. Although results are preliminary, this new approach represents a potential breakthrough in the treatment of hyperpigmentation because the skin-lightening formulation does not include the more toxic hydroquinone and can thus be used safely in women of

**Figure 58-3 A,** Baseline appearance of patient with Fitzpatrick phototype IV skin and melasma. **B,** Same patient after four SilkPeel treatments combined with dermalinfusion of Lumixyl, a novel skin-lightening formulation that does not contain retinoids or corticosteroids.

child-bearing age, even if pregnant or breast-feeding. In addition, results from the pilot study indicate that no skin irritation or skin thinning would be expected from this treatment because the formulation does not include retinoids or corticosteroids, respectively. Figure 58-3 shows the results for an Asian patient with Fitzpatrick type IV skin before and after four weekly treatments using this approach.

# Other Dermalinfusion Systems

HydraFacial, manufactured by Edge Systems (Signal Hill, Calif), is another dermalinfusion unit currently used by dermatologists and aestheticians. Similar to SilkPeel, the HydraFacial device simultaneously resurfaces the stratum corneum and delivers active serum into the treated tissue. The exfoliation is achieved with a patented crystal-free tip, patented disposable HydroPeel tip, or a Spa Aggression tip. Various skin-specific solutions such as glucosamine, lactic acid, salicylic acid, and antioxidants (vitamins A and E and white tea extract) are used for infusion. The Tissue Nutrient Solution (TNS) serum developed by SkinMedica (Carlsbad, Calif) is exclusively designed for the HydraFacial system. The serum consists of NouriCel-MD, a patented formulation of human growth factors, cytokines, soluble collagen, antioxidants, and matrix proteins that enables greater skin rejuvenation.

In a study by Freedman (2008), two study groups were randomized to either a series of hydradermabrasion treatments with antioxidant dermalinfusion or treatments with the same antioxidant applied manually. Histologic and clinical assessments showed improvement in skin quality in the hydradermabrasion group. The treated skin showed in a statistically significant increase in antioxidant levels and an increase in epidermal and papillary dermal thickness, collagen hyalinization, and fibroblast density. There was also a decrease in wrinkles, pore size, and hyperpigmentation after hydradermabrasion treatment. The skin with manually applied antioxidant, however, showed no detectable change in structure or antioxidant levels. MDA with antioxidants as an infusion agent may be a reasonable treatment option for those patients who wish to prevent or stop the signs of aging.

In another study by Freedman (2009), 10 patients were treated in split-face fashion with either MDA with infusion of an antioxidant serum or MDA alone. Patients underwent a total of six treatments, each 1 week apart. Histologic assessment of post-treatment biopsy samples revealed that patients treated with MDA plus antioxidants had a marked increase in epidermal and papillary dermal thickness, as well as an increase in fibroblast density and deposition of collagen. Digital photography indicated that skin quality improved more with the combined treatment than MDA alone. Raman spectroscopy was used to measure skin polyphenolic levels. The

dermalinfusion-treated skin was found to have a 32% increase in antioxidant levels. Unfortunately, the author did not report the effect of MDA alone on polyphenolic levels, so it remains unclear whether the increase in antioxidant levels is attributable to topical infusion therapy, MDA, or a combination of the two. Further studies are required to clarify this issue.

Although a number of other MDA infusion systems have been commercially developed, only the HydraFacial and SilkPeel systems have appropriate patent protection. Therefore, no other systems are reviewed in this chapter.

#### **CONTRAINDICATIONS**

SilkPeel has been safely used in patients with inflammatory disorders such as psoriasis or eczema without complication. This is due to its ability to abrade up to specific depths by altering the grit of the diamond used for abrasion. Other MDA systems have not been reported to share this safety advantage. Similarly, many practitioners are using MDA for the treatment of actinic keratoses. However, frank malignancy is a contraindication because of fear of spread of the lesion after treatment. It should be noted that this concern is theoretical and not based on any published reports.

Absolute contraindications to MDA include the following:

- Accutane use within the past 12 months (except SilkPeel)
- Presence of skin malignancy (excluding actinic keratoses; see earlier discussion)
- Presence of herpetic lesion(s)
- Presence of eczema or psoriasis (except SilkPeel)
- Presence of autoimmune disease

Relative contraindications to MDA include the following:

- Accutane use within the past 12 months (for SilkPeel only)
- Patients with thin skin
- Patients with compromised wound healing (e.g., smokers, diabetic patients)
- Patients with compromised immune systems
- Current use of anticoagulation therapy (excludes diamond-based MDA)

#### **PATIENT SELECTION**

Microdermabrasion is safe and effective; however, proper patient selection is essential. Poor patient selection will cause patient dissatisfaction, staff frustration, and ultimate failure of the MDA program in any given practice.

MDA is an excellent modality for all skin types, even those patients with Fitzpatrick skin types V and VI (see Chapter 46, Introduction to Aesthetic Medicine). These patients are especially vulnerable to hyperpigmentation or hypopigmentation when more aggressive skin resurfacing treatments are administered. MDA is safe in these patients because the depth of penetration is usually limited to the superficial epidermis. Elderly patients with thin skin are not good candidates for MDA unless pretreated with other modalities to improve skin quality. Pregnant women should not undergo MDA because of hormonal changes that cause increased skin sensitivity, delayed wound healing, and increased melanocyte melanin production. Consequently, the risk of PIH and scarring can be significant during pregnancy, and any procedure should be avoided until after delivery. Patients on anticoagulant therapy are also not good candidates for crystal-based MDA and should be treated with caution because it can be difficult for the practitioner to adequately control the abrasion depth, potentially injuring blood vessels in the papillary dermis and causing excessive bleeding.

It is recommended that patients who have had a recent chemical peel or other skin procedure such as collagen injections, waxing, tanning, or sun exposure wait at least 2 weeks before undergoing MDA.

#### **INITIAL EVALUATION**

Every patient must be seen and evaluated by the physician before initiation of a treatment protocol. Unfortunately, some offices turn the MDA practice over to an aesthetician and the process runs independent of physician input. This situation is more appropriate for a beauty salon. A physician has the responsibility of seeing and evaluating every patient who is treated in his or her practice. Anything less than this compromises patient care.

After filling out the usual history form, with special attention to current medications, the physician should evaluate the patient with particular attention to the following:

- Fitzpatrick skin typing (see Chapter 48, Lasers and Pulsed-Light Devices: Hair Removal)
- Skin thickness
- Skin tone
- Site-specific rhytids
- Depth and severity of rhytids
- Drvness
- Acne
- Acne scarring
- Other scarring
- Vascular anomalies
- Telangiectases
- Ecchymosis
- Nevi
- Pigmentation problems
- Skin malignancies
- General actinic damage
- Actinic keratoses
- Current tanning status
- Poikiloderma
- Open sores
- Herpetic lesions

Once these and other individual factors are considered, a treatment protocol can be determined for the patient. Instructions should be written or checked off on a patient encounter form and communication with the MDA technician concerning the patient's treatments completed (Fig. 58-4; also see Chapter 46, Introduction to Aesthetic Medicine, Fig. 46-1).

Pretreatment and post-treatment photographs are recommended and are a part of the patient's permanent record. They will also facilitate assessment of clinical outcomes. However, do not expect miracles with every patient. It may be extremely difficult to photographically document improvement in patients whose initial skin quality is good and who just wanted "freshening." Certainly, those patients with major pigment problems, acne scarring, and other extreme conditions yield documentable photographic improvement. More recent advances in digital photographic systems will provide improved sensitivity, allowing detection of less dramatic improvements in patients with reasonable baseline skin quality.

# **COMPLICATIONS**

Complications can result from any type of treatment, regardless of how innocuous the technology may seem. Certainly, MDA is no different. However, the very factor that has contributed to MDA's widespread success is that it has very few, if any, long-term complications. The physician and staff should receive bona fide training before embarking on patient treatments and know the potential complications and treatment options to provide a good outcome.

Erythema is the most common side effect of MDA, and its severity has a nearly linear relationship with the aggressiveness of the treatment. Some patients (e.g., those suffering from dermatographism, rosacea, or certain types of urticaria) have very sensitive skin and will exhibit some erythema no matter how mild the treatment settings. Most erythema resolves spontaneously within a few hours.

Initial Photographs:

Figure 58-4 Sample form: Chemical peel/microdermabrasion new patient consultation checklist. (Courtesy John L. Pfenninger, MD/The Medical Procedures Center, Midland, Mich. Adapted from various sources.)

Inform the patient to avoid sun or tanning bed exposure during the time of his or her treatment sessions because this will surely increase skin irritation. All patients must use daily sunscreen (preferably SPF 30 or greater) to protect their skin.

Most patients experience mild tingling, which is very tolerable. However, a few patients complain of burning and skin discomfort for up to 24 hours after the peel. These patients can be treated effectively with moisturizers.

Purpura, ecchymosis, and petechial hemorrhages are all a function of overly aggressive vacuum settings. They are more common with crystal-based MDA treatments and relatively uncommon with diamond-based ones. Also, poor patient selection, such as treating patients with thin skin or those on anticoagulants (gingko, vitamin E, aspirin, and nonsteroidal anti-inflammatory drugs, among others), can lead to these side effects. Apply ice to the area when first noticed and decrease the vacuum setting to minimize the problem. If one of these complications should occur, do not return to the affected area for peeling at that same treatment session. Skin should return to normal appearance in most patients younger than 50 years of age within 10 to 14 days. It may take longer to resolve these problems in older patients.

Scarring is rare with MDA, but can occur in the following unusual situations:

- Patient circumstance demands aggressive therapy (e.g., treatment of mild to moderate acne scarring on the cheeks, which requires deep planing).
- Aggressive treatments administered to patients currently using Accutane or patients who have been on Accutane within 1 year of initiating MDA.
- Mild skin abrasion in patients who are noncompliant, have compromised immune function and subsequent wound contamination, or have active infection.
- Being too aggressive or allowing the handpiece to stop or dwell on specific skin areas for too long.

Minor skin abrasions can easily occur. Simply having the patient clean these areas and apply petroleum jelly or antibiotic ointment until reepithelialization has occurred should alleviate the situation.

Ocular damage is a potential complication. Protection of the eyes for both the patient and practitioner is absolutely essential. Tsai and associates (1995) discussed development of ocular pain, photophobia, epiphora, and conjunctival congestion with crystal adherence to the cornea and punctate keratopathy resulting from ophthalmologic crystal contamination during MDA. Ocular contamination can be prevented by placing moist, folded  $4 \times 4$  gauze pads over the eyes and holding them in place with suntanning goggles. Alternatively, special eye shields (see next section) can be used alone. After treatment, the technician must meticulously remove crystals from the periorbital region before allowing the patient to get off the treatment table and wash.

#### **EQUIPMENT**

- MDA unit with tips (sterile, reusable metal; plastic disposable; Fig. 58-5)
- Power examination table and adjustable stool for the technician
- Alcohol wipes
- Crystals (usually aluminum oxide); approximately one-half of a cup (30 to 35 mL) for the face and more for larger areas
- Nonsterile gloves
- Moist 4 × 4 gauzes
- Surgical cap for patient
- Suntanning goggles for patient (alternatively, Derm-Aid Non-Laser Disposable Eye Shields [GPT Glendale, Inc., Lakeland, Fla] work very well)
- Saline eye wash
- Towel or gown to drape around patient's neck
- Protective glasses with shields for operator
- Mask for operator (to reduce inhalation)
- Postoperative moisturizer (e.g., Theraplex, aloe, Kinerase) and sunscreen (with zinc or titanium)
- Flow sheet to record settings and progress
- Digital camera with macro feature for close-up pictures (ideal but optional)
- Solutions to be used for dermalinfusion (contact manufacturers)
- Cleaning solutions (contact manufacturers)

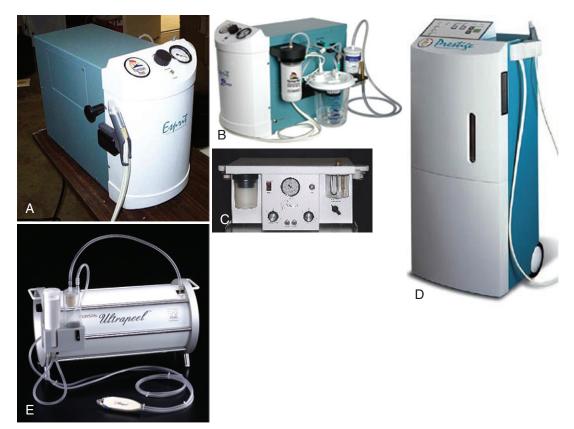

Figure 58-5 A, Parisian Peel Esprit. B, Inside view of Parisian Peel unit showing the crystal container and collection system. C, BellaMed microdermabrasion machine. D, Prestige microdermabrasion machine. E, Ultrapeel Crystal. (A, B, and D, Courtesy of Aesthetic Technologies, Broomfield, Colo. C, Courtesy of Bella Products, Foothill Ranch, Calif. E, Courtesy of Saratoga Diagnostics, Saratoga, Calif.)

Crystals vary widely in quality and cost. Cheaper materials contain variable-sized particles and may not be pure. Fine, powdery substances are not only less effective but aerosolize when the containers are emptied. Not only do these substances cause a sediment in the room, they may be irritating to the patient or clinician. The lower limit of particle size should be 20  $\mu$ m. Crystals should also be prepared in a "medically clean" way to avoid any type of contamination.

The apertures that the crystals traverse eventually wear larger from the crystal passage. Check to see if the tip needs repair/replacement before each treatment by observing the crystal flow. A wider crystal flow that lacks uniformity indicates the need for tip replacement.

Handpiece tips must be replaced or sterilized (cold or hot) for each patient. Angled handpieces are somewhat more comfortable for the operator to use.

# PREPROCEDURE PATIENT PREPARATION

- Have the patient wash his or her face to remove all makeup and lotions
- The patient must wear eye protection and a surgical cap to keep crystals from getting into the eyes and hair. Should crystals get into the eye, they can be very irritating and must be washed out with saline.
- The patient is placed in the supine position on the treatment table. The technician is seated at the head with clear three-sided access to the patient.
- Place a towel or gown around the patient's neck to keep crystals from getting on the patient's clothing.
- Cleanse the patient's face with isopropyl alcohol or acetone to remove any lingering skin oils, makeup, and lotions.

 Examine the skin in the areas to be treated. Open sores should be avoided. Also, be attentive for any type of herpetic outbreak. If the patient does exhibit a herpetic lesion, cancel the treatment for at least 2 weeks and make sure the patient is treated with the appropriate antiviral medication (e.g., Valtrex, Zovirax). Prophylaxis for patients with frequent herpetic outbreaks may be required; however, it should be individualized to each patient's circumstance.

# **TECHNIQUE**

See specific manufacturers' guidelines for each particular unit.

- 1. Select the appropriate grit and size of the diamond-tip treatment head. The heads vary in coarseness from smooth (no diamond chips) to fine (120 grit) and coarse (30 grit). The 6-mm head is recommended for the face and the 9-mm head for larger areas such as the arms and legs. The usual power setting for initial treatment starts at 12 to 14 mm Hg and works up to 18 to 20 mm Hg for most patients (those with special problems such as acne scarring may require 20 to 35 mm Hg). *Tip*: The practitioner can make a good estimate of the correct suction level by applying the handpiece to a colored page from a magazine for 3 to 4 seconds. If all color is removed, the power is too high. If most is removed, it is just right. If most color is left, it is too low.
- 2. With a nonsterile, gloved hand, spread the skin between the thumb and index or middle finger with a moderate amount of tension. Place the MDA treatment head on the skin and move the handpiece parallel to the direction of tension between the two fingers (Fig. 58-6A). Keep the handpiece head moving, and definitely avoid stopping and holding it in contact with one area

**Figure 58-6 A,** First microdermabrasion pass on the patient's right cheek. The technician's fingers are tensing the skin in a horizontal direction while using parallel movements of the handpiece. **B,** A second pass on the right cheek with the skin tensed in a more vertical orientation, perpendicular to the direction of the first pass in (**A**). Note crystal residue on skin.

of the skin; this could cause deep penetration and seriously damage the skin and cause scarring. Hold the handpiece perpendicular (90 degrees) to the skin.

- 3. For the first pass, strokes should be from the central face to the periphery. After completing a small area of skin with parallel strokes, move the handpiece for a *second pass* perpendicular to the direction of movement of the first pass (Fig. 58-6B). This crosshatches the area and decreases any streaking or linear erythematous markings. It is recommended to start at the forehead, proceed down the bridge of the nose, and cover the cheeks, chin, and around the mouth.
- 4. If a third pass is to be made, use a circular or swirling motion. When initiating MDA with a new patient, it may be prudent to see how two passes are tolerated and their effects before making a third.
- 5. After two or more passes, some patients exhibit a darkened or grayish hue to the skin because of the crystal interaction with skin oils. This is no cause for alarm because it will be removed completely with post-treatment cleansing. (For treatment of the neck, only one pass with vertical strokes is sufficient. For treatment of the chest, use two passes with strokes from the midline to the periphery. For treatment of the hands, have the patient make a fist around a towel and perform two passes with strokes parallel and then perpendicular to the axis of the forearm.)
- 6. When the treatment is completed, the technician should remove the crystals from the face while the patient is still in the supine position, taking great care to remove all crystal remnants from the periorbital region by suction or gentle removal with a moist cloth.
- 7. Have the patient cleanse with mild soap and water.
- A light moisturizer, such as aloe, Theraplex, or Kinerase, will decrease any mild irritation. Also apply sunscreen with SPF 30 or greater (containing zinc or titanium).

After a treatment, it is important to leave the crystal container heater on whenever the machine is not in use to prevent moisturization of the crystals, which would result in poor crystal flow and possible malfunction.

# **POSTPROCEDURE PATIENT EDUCATION**

Instruct the patient to avoid applying makeup, if possible, for the next 12 to 18 hours and to avoid significant sun exposure for 3 to 4 days after each treatment. The patient must wear sunblock whenever going outdoors and avoid applying irritant products such as retinoids, astringents, alpha-hydroxy acids, and depilatories for 1 week. See the sample patient education form online at www. expertconsult.com.

# **PURCHASING A MICRODERMABRASION SYSTEM**

Before purchasing an MDA machine, consider several factors:

- Do you currently have access to a patient base that is appropriate for the use of this technology?
- Can ancillary treatments or therapies be offered to enhance the patient's results and to generate additional income (e.g., skin care products)?
- Do you have the personnel to support these new activities?
- Do you have the office space to dedicate to the MDA unit and a practitioner for the procedure?
- Make sure the local region is not saturated with MDA units. Is there a realistic market potential?
- Evaluate machine functions such as crystal flow, vacuum capacity, and the operator's ability to vary treatment parameters.
   Machine flexibility is important in treating a variety of skin types, conditions, and problems.
- Evaluate the propensity of the machine to clog, which may occur in a humid, moist environment. Most machines have a crystal heater that maintains dry crystals. The heater is left on continually.
- In today's market, warranty coverage, technical support, and possible shared marketing arrangements have become increasingly important factors in determining purchase decisions.
- Along with designated staff, attend a course that covers the essentials of MDA. These courses are usually sponsored by the equipment manufacturer or physician experts in the field.

# SKIN PEELS

Cathy Uecker

With the tremendous increase of older Americans as the "baby boomer" population ages, more and more patients are seeking treatments for photodamage and other conditions commonly seen with aging skin, such as uneven color, tone, and texture. In fact, skin rejuvenation has become one of the most common reasons for patients to consult a plastic surgeon, dermatologist, or clinical skin care provider. Oral isotretinoin (Accutane) prevents much of the deep scarring once seen from acne. However, patients routinely request treatment for minor scarring and postinflammatory hyperpigmentation, usually the result of previous acne lesions. Chemical peels and topical medications continue to be reliable methods used to rejuvenate skin damaged by all of these conditions.

Superficial peels are very common and are deemed so safe that nonclinicians now perform them in health spas and salons. However, many patients would prefer to have even superficial peels performed under the trusted supervision of their primary care clinician if the procedure were made available to them.

Although skin aging is both intrinsic (Table 59-1) and extrinsic (Table 59-2), the majority of damage is from extrinsic causes. *Intrinsically*, chronic use of the muscles of expression and dermal thinning with the loss of collagen fibers due to aging produce wrinkles and skin lines. Most intrinsic aging, such as that associated with hormonal changes, is the result of both chronologic and genetic causes.

Extrinsic aging is caused by environmental hazards, such as ultraviolet radiation, wind, smoking, and chemical exposure. Years of exposure from the sun and tanning booths can produce wrinkles and pigmentary or surface changes. The stratum corneum thickens and the granulosum and spinosum layers become thinner. Atypical cells develop, the skin becomes less translucent, and pigmentation often becomes markedly irregular. Lentigines (freckles) and actinic precancerous lesions may develop (Fig. 59-1), the papillary dermis thins, and the skin loses elasticity while developing a sallow color. Extrinsic aging causes blood vessels to dilate, telangiectases to proliferate, and collagen to become sparse (clumping in bundles). In turn, the reticular dermis fills with abnormal elastin fibers. Eventually, hair follicles and pores dilate and become filled with desquamated debris.

In America, from the early 1900s until the 1950s, chemical peels were popular for skin rejuvenation. When dermabrasion was developed in the 1950s, it soon became the favored skin resurfacing technique. With newer commercial preparations available and America's "baby boomers" aging, yet able to afford cosmetic treatments, chemical peels became popular again. Recent developments in cryotherapy and laser have also become available for more complex interventions.

# TOPICAL TREATMENTS AND ADJUNCTS TO PEELS

Considerable improvements in sun-damaged skin can be achieved with topical therapy alone if the patient is willing to be consistent and compliant with a skin care program. Topical retinoids, such as tretinoin (Retin-A), have been shown to clinically and histologi-

cally reverse sun damage. In fact, the more severely damaged the skin, the better the response. Newer tretinoin products have gained popularity owing to advances in their delivery systems geared toward reducing the common side effects of dryness and irritation. For example, Renova (Ortho Dermatologics, Skillman, NJ) is delivered in an emollient base. Retin-A-Micro (Ortho Dermatologics) has a patented microsphere delivery system, and Atralin (Valeant Pharmaceuticals, Aliso Viejo, Calif) is delivered in a water-base, alcoholfree vehicle, with added hydrating and moisturizing ingredients. Compliance and consistency with topical therapy are much greater when dryness and skin irritation are decreased. After the use of topical retinoids, biopsies demonstrate deposition of new dermal collagen, formation of new blood vessels, and normalization of epidermal atypia. Accumulated melanin in the basal layer is transported to the surface and shed, improving pigmentation. Epidermal cell turnover is stimulated, producing a proliferation of new cells and improving skin texture. Improved blood supply to the dermis enhances both skin color and the transportation of nutrients to the skin. However, a minimum of 24 weeks is necessary to manifest visible signs of improvement. Unfortunately, topical treatments must continually be used to maintain improvements. When topical treatments are discontinued, the skin gradually returns to its previous condition.

Fortunately, retinoids are now available generically, so their cost has decreased; however, some dermatologists insist that the generic preparations have a higher risk of skin irritation because of their preservatives. Those likely to benefit the most from retinoids are fair-skinned individuals in their 30s and 40s who have blotchy pigmentation, sunspots, or fine lines around their eyes.

Lustra (Medicis Pharmaceuticals, Phoenix, Ariz) is an antiaging cream that contains 2% glycolic acid, antioxidants, and 4% hydroquinone. Hydroquinone, a tyrosinase inhibitor, disrupts the synthesis of melanin, thus lightening the skin or pigmented areas. It is also available in a preparation that contains a complete sunblock (Lustra AF). This type of preparation can be used in combination with topical retinoids to treat areas of hyperpigmentation, such as melasma. Use of a combination of topical preparations is likely to be slightly irritating to the skin. To avoid irritation that may cause

# TABLE 59-1 Intrinsic (Chronologic and Genetic) Aging of the Skin

Cause	Effect
Decreased vascularity Dermal thinning Decreased dermal cellularity Loss of elastic fibers Decreased mechanical properties with decreased elastic recoil after stretching	Yellow skin Atrophy Irregular texture Fine lines or wrinkles Laxity

TABLE 59-2	Extrinsic	(Solar	and	Environmental)
Aging of the	Skin			

Aging of the skin	
Cause	Effect
Altered cell maturation	Dry, coarse texture, actinic keratoses
Melanocyte alteration (overstimulated or destroyed)	Solar lentigines, mottled pigmentation
Decreased collagen fiber number and strength; elastic fiber curling, branching, and thickening; degeneration into solar elastoses	Fine wrinkling
Loss of collagen support of vessels Alteration of vascular network	Solar (senile) purpura Yellow hue, loss of pink color

Adapted from Lewis AB, Gendler EC: Resurfacing with topical agents. Semin Cutan Med Surg 15:139–144, 1996.

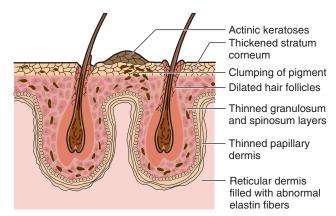

patients to discontinue their regimen, it is wise to start with everyother-day application for the first 2 weeks, and then daily.

If skin irritation occurs and becomes problematic, a mild steroid cream or ointment (triamcinolone 0.1%), applied sparingly and concomitantly once a day, may reduce the associated erythema and flaking.

α-Hydroxy acids (AHAs) can be applied at low strength (2% to 20%) by patients as part of their daily skin care regimen to improve collagen and elastin synthesis and promote protein regeneration. AHA is a "blanket" term for a variety of fruit acids. Studies have indicated that both the papillary dermis and the epidermis can be thickened, elastic fibers improved, and melanin dispersed with the use of AHAs. Benefits visible to the patient include the reduction of fine lines and wrinkles along with improved skin color, tone, and texture. At low doses these occur without inflammation. Because AHAs do not cause angiogenesis (as opposed to retinoids), they are the preferred treatment for patients with telangiectases from rosacea. In addition, because AHAs work by a different mechanism, they can be used concurrently with retinoids.

The following is a list of some of more commonly used AHAs or ones you may see as ingredients in skin care products:

- Glycolic acid (GA): Derived from sugar cane, by far the most common and widely used. Because it has the smallest molecular size of all the AHAs, it easily penetrates the skin and is often used as a delivery system in skin care products.
- Lactic acid: Comes from sour milk and is used as a skin softener and exfoliator.
- Citric acid: Vitamin C is most commonly used as an antioxidant.
- Malic acid: Derived from unripe and green grapes.

**Figure 59-1** Skin damage from years of sun exposure. (Redrawn from Edwards L, Maibach HI, Roenigk HH: What can be done for photoaged skin? Patient Care 30:68, 1996.)

- Tartaric acid: A fermentation byproduct from wine making.
- Mandelic acid: Derived from almond extract and has antibacterial properties. It is a larger molecule than GA, making it widely tolerated by almost all skin types.

Because of increased sun sensitivity, retinoids are usually applied at night, whereas AHAs are most often applied during the day, along with the recommendation of a sun protection product with an SPF of 15 or greater. Skin texture, and to some degree skin pigmentation, may benefit at any age from retinoids, AHAs, or both. If irregular or abnormal pigmentation is persistent, consider incorporating *hydroquinone*, a tyrosinase inhibitor, or *kojic acid*, a melanin inhibitor, to the patient's treatment program.

There are many AHA preparations available, buffered to various pH levels. It has been theorized that the beneficial or antiaging effects of AHAs are due to activation of transforming growth factor- $\beta$ , which is increasingly activated at cutaneous pH levels below 5. The prolonged application of "acid" AHAs may reduce the cutaneous pH and thus activate this growth factor. Most unbuffered AHAs have a low pH; however, a low pH also increases the risk of local skin irritation. Buffered preparations with pH levels above 2 are available and may be preferred if skin irritation occurs. In addition, using a low-strength AHA before a chemical peel not only will allow the clinician to judge patient tolerance, but will enhance the penetration of the peel.

# ALTERNATIVE PROCEDURES TO CHEMICAL PEELS

Alternatives to chemical peels include the following:

- Cryopeels
- Dermaplaning
- Dermabrasion
- Microdermabrasion/dermalinfusion
- Ablative laser resurfacing
- Fractional ablative laser resurfacing
- Nonablative laser (intense pulsed light [IPL])

Of the alternatives to chemical peels, *cryopeels* are the most similar in effect (see Chapter 14, Cryosurgery). Many primary care clinicians already use liquid nitrogen for freezing pigmented spots (lentigines), warts, actinic keratoses, seborrheic keratoses, and angiomas. With considerable experience, and often aided by a special attachment, the clinician can treat the entire face with cryotherapy to produce a cryopeel. It is less expensive for the patient than having a deep chemical peel, and with proper patient selection results may last up to 1 to 2 years. Although a cryopeel may result in more swelling initially, results are often comparable with those of a medium-depth chemical peel.

Originally designed to remove acne scars, surgical skin planing, or dermaplaning, was soon found to be useful for scarring from other causes, such as photodamage. After freezing, the skin layers are removed mechanically. Although postoperative healing is slower with dermaplaning and the cost is much higher than for a peel (as much as \$4000 for a full-face dermaplane), more severe lesions can be treated, and the results of the skin resurfacing last longer (5 years or more). A more common and less invasive dermaplaning procedure is accomplished by scraping the skin with a no. 12 blade. After cleansing the skin, a light coating of povidone-iodine (Betadine) is applied and allowed to dry. Visualizing the change of color while gently scraping the skin allows the clinician to carefully remove only the most superficial layers of the epidermis. Repeat treatments may be done every 4 to 6 weeks at a cost of \$150 to \$200 per treatment. Although chemical peels are the procedure of choice for fine wrinkles, dermaplaning has a more prolonged effect and is superior for deep acne scars. Dermabrasion is similar to dermaplaning (e.g., preparations, indications) and is most often used to improve the look of facial scars caused by accidents or previous surgery or to smooth out fine facial wrinkles. The patient should be aware that after dermaplaning or dermabrasion, the immedicate postprocedure effects on the face will be quite obvious to friends and colleagues, with an average downtime of at least 10 to 14 days or even longer.

Microdermabrasion (see Chapter 58, Microdermabrasion and Dermalinfusion) is a technique in which the skin is buffed with aluminum oxide crystals. This method has grown in popularity because there is virtually no downtime. It has been coined "the lunchtime peel" and it is much less expensive than dermabrasion (about \$50 to \$100 per treatment). Three to six treatments are needed at weekly intervals for significant results. Among aesthetic skin care providers, microdermabrasion is the closest equivalent to superficial facial chemical peels. A potential drawback for primary care clinicians is the initial cost of \$3500 to \$10,000 for equipment.

Carbon dioxide laser resurfacing is another option. Traditionally, lasers were used to obtain a deep resurfacing that often required general or tumescent anesthesia. The cost was as much as \$3500 to \$5000 per treatment. Although studies have not been published comparing laser surgery with dermabrasion, anecdotal evidence indicates it to be as effective as dermabrasion for removing deep wrinkles around the mouth. There have been no comparative studies showing advantages of laser resurfacing of the whole face over dermabrasion or chemical peeling.

Long-pulse (i.e., 1000 milliseconds) erbium-YAG lasers and CO<sub>2</sub> lasers are now being used to achieve results similar to superficial and medium-depth chemical peels. Using special techniques (fractional ablation techniques), islands of skin are left unaffected within the treated area. This leads to a more rapid recovery time (5 to 7 days) as opposed to previous laser therapy (6 weeks). These lasers can be used anywhere on the body with only topical anesthesia and some oral sedation (see Chapter 51, Lasers and Pulsed-Light Devices: Skin Tightening, and Chapter 53, Fractional Laser Skin Resurfacing). These units require a considerable investment (\$70,000 to \$140,000).

With the exception of ethnically darker skin types, IPL therapy works best for pigment reduction, redness, flushing, or dilated capil-

laries, and can also be used for overall skin rejuvenation. There is no downtime for patients and minimal discomfort during the four to six required treatments. Unfortunately, the cost of equipment (\$40,000 to \$80,000) again prevents many primary care clinicians from offering this procedure. Certain IPL technologies can also be successful for hair reduction. However, if using IPL therapy for hair reduction, Fitzpatrick skin types IV through VI will present a challenge in both treatment safety and efficacy (see Chapter 39, Epilation of Isolated Hairs [Including Trichiasis]).

# **CHEMICAL PEELS**

If self-applied over-the-counter AHAs alone are unsatisfactory, they can be used at higher strengths (20% to 70%) or with other agents to cause an inflammatory response or a skin peel. Chemical peeling relies on penetration of an irritating exfoliant into the dermal level to produce a controlled-depth wound that results in sloughing of the superficial skin layers of the epidermis. The injury also evokes a nonspecific tissue regeneration that produces a smoother and more youthful-appearing skin. A peel can be used after the skin has been prepared over time with retinoids, AHAs, or both, or it can be used as an alternative to the continuous application of these topicals.

It is not surprising that AHAs improve the skin; fermented food products that contain them have long been used to exfoliate the skin. Ancient Egyptians used the "hemayet" fruit, Greeks used facial masks, and Romans applied various combinations of salts and plants for this purpose.

Four levels of chemical peels are available: (1) *superficial*, (2) *superficial to medium*, (3) *medium*, and (4) *deep* (Table 59-3). The deeper the peel, the higher the risk of complications, patient inconvenience, and discomfort. A downtime of 1 or 2 weeks is to be expected with medium-depth and deeper peels, and it is usually obvious to the patient's friends and colleagues that a cosmetic procedure has been performed. On the other hand, most superficial peels can be performed on a Thursday with the patient able to return to work the following Monday with little noticeable skin damage.

TABLE 59-3 Levels of Chemical Peeling					
Type of Peel	Chemical Formula	Indications			
Superficial, stratum granulosum/papillary dermis (up to 0.06 mm)	AHA (GA 20%–70%) BHA (SA 20%–30%)	Fine rhytides (wrinkles)			
,	5-Fluorouracil TCA (10%–20%)	Bad skin texture			
	Jessner solution: 14 g resorcinol 14 g SA 14 g lactic acid	Acne vulgaris (comedonal/inflammatory, papular-pustular)			
	95% ethanol (quantity sufficient to add up to 100 mL)	Acne rosacea (papular-pustular)			
	Unna's paste Carbon dioxide (solid)	Pigmentary changes (especially postinflammatory) Superficial actinic keratoses			
Superficial to medium (0.06–0.45 mm)	20%–30% TCA Series of AHA (GA 20%–70%) or BHA (SA 20%–30%) peels (see Table 53-4)	Persistent fine rhytides or bad skin texture Persistent acne vulgaris or rosacea Persistent mild pigmentary changes Isolated but deeper actinic keratoses			
Medium, upper reticular dermis (0.45–0.6 mm)	50% TCA or 35% TCA plus initial keratolytics Initial keratolytics: Jessner's solution, carbon dioxide (solid), or 70% GA	Moderate rhytides (wrinkles) Chronic photodamage Multiple epidermal/premalignant lesions Pigmentary changes and solar lentigines Multiple actinic keratoses Multiple flat warts			
Deep, mid-reticular dermis (0.6–0.8 mm)	Baker-Gordon formula: 3 mL 88% phenol Three drops croton oil Eight drops hexachlorophene 2 mL distilled water	Severe rhytides (wrinkles) Epidermal lesions Superficial neoplasms Deep pigmentary changes			

AHA,  $\alpha$ -Hydroxy acid; BHA,  $\beta$ -hydroxy acid; GA, glycolic acid; SA, salicylic acid; TCA, trichloroacetic acid.

Because of the potential for postinflammatory hyperpigmentation, scarring, and hypopigmentation, superficial peels are the procedure of choice for individuals with ethnically darker skin.

**NOTE:** With the ability to achieve many of the effects of deep peels by repeated superficial peels combined with retinoid preparation, the need for deep peels has diminished. For this and other reasons (including a higher risk of permanent skin damage and scarring with deep peels), deep peels should be performed *only* by someone formally trained or significantly experienced in advanced peels. For this chapter, deep peels are discussed only for the sake of completeness and to provide the clinician with an understanding of older, alternative techniques.

Although chemical peels are the least complex of the many cosmetic procedures discussed here, they should not be taken lightly or performed without proper training, experience, and knowledge of managing potential adverse events. With chemical peels, there is less control of the depth of skin penetration and damage than with other skin procedures; therefore, in unskilled hands it is wise to start with superficial peels. Deeper peels should not be performed until the clinician has significant clinical experience with various peeling agents.

Advantages of chemical peels over dermabrasion and laser include the lower cost of equipment and a shorter learning curve, especially for superficial and medium-depth peels.

Various chemicals have been used for skin peels, also known as chemexfoliation and chemabrasion, in addition to AHAs. These include phenol, trichloroacetic acid (TCA), and  $\beta$ -hydroxy acid (BHA; i.e., salicylic acid [SA]). Combinations are also used. For single agents, lactic, glycolic, and salicylic acids are used most frequently. The difference between BHA and AHA is that AHAs are water soluble, whereas SA (the only BHA) is lipid soluble.

Weaker chemicals such as *resorcinol* have been used and are relatively free of side effects. Resorcinol is rarely used alone; it is most commonly used in Jessner solution (see Table 59-3).

The effects of a single light peel are so subtle that friends, colleagues, and even the patient may not realize that a cosmetic procedure has been performed. For greater patient satisfaction, a series of peels or alternating superficial peels with microdermabrasion treatments is recommended.

Glycolic acid is often the first choice of experts for skin peels. Among the many benefits of using GA is the fact it is stable and water soluble. In addition, GA is colorless, odorless, and nontoxic if ingested. Disadvantages of GA include the fact that the peels are somewhat variable: some patients have a brisk inflammatory response to only 30% GA, whereas others have only a slight response to as high as 70% GA. There is some dispute concerning the degree of buffering to be used with GA. Even though it is water soluble, some controversy also exists on how best to neutralize it after application.

Salicylic acid is "self-limiting" and does not require neutralization after application. Another benefit of SA over GA or any of the AHAs is that the end product is a visible precipitate, or "frost," after application. This allows the clinician to verify that the application is even. If a frost is not clearly visible after the application of one coat, and drying time has been allowed, an additional coat can be applied. SA fluoresces under a Wood's light, which can be used to ensure complete application. These characteristics may be important when clinicians are first learning the procedure. Because it penetrates the epidermal lipids of the skin more deeply than GA, SA usually causes more desquamation (allowing patients to see the peeling and note the changes).

In addition, because SA is lipid (oil) soluble it is naturally comedolytic and is able to penetrate into the pore and exfoliate the buildup of sebum and dead skin cells. Therefore, it is perhaps the best preparation to use with acne rosacea.

With these differences, it would appear that SA is superior to the AHAs; however, in reality most experts do not use these

differences to make their choice, but rather their own personal experience.

TCA, AHAs, and SA (at the listed strengths) are not as deeply absorbed through the skin and do not burn the skin nearly as deeply as *phenol*. Therefore, once the clinician is adequately trained on proper patient selection, the application process, and how to manage potential adverse events, using only these preparations avoids most of the long-term sequelae associated with deep phenol peels (e.g., total loss of pigmentation, irregular pigmentation, hypertrophic scars). Because of these risks and a theoretic risk of toxicity if absorbed, phenol peels are used much less frequently than other modalities.

With safe and effective AHA and SA peels available, there is a question as to whether primary care clinicians should even use TCA or phenol, both of which work by coagulating skin proteins. Decreasing the concentration of TCA toward 20% decreases the depth of exfoliation, perhaps making it safer. Before the advent of AHAs and BHA (i.e., SA), TCA was found to be safer than phenol for treating transition zones, such as the area between the face and neck. It was also found to be excellent for treating the thin skin of the hands. In both of these areas, a deeper burn might increase the risk of scar formation.

With AHAs, application of a series of superficial peels, especially if the skin has been prepared by the use of topical retinoids for many weeks, may produce the same effects as one medium peel or even some of the effects of a deep peel. With experience, AHAs allow you to customize the treatment to the area of the body.

# **INDICATIONS**

See Table 59-3.

- Skin rejuvenation—freshen and brighten skin
- Minor to moderate photodamage, especially in 25- to 50-year-old patients
- Dissatisfaction with results from home topical therapy program alone
- Irregular skin texture
- Actinic keratoses
- Acne vulgaris (comedonal and inflammatory, papular and pustular)
- Acne rosacea (papular and pustular)
- Irregular pigmentation (e.g., melasma, freckles, hyperpigmentation, lentigines)
- Superficial acne scars
- Fine wrinkles
- Multiple flat warts

**NOTE:** If peels are used to treat acne or the complications of acne, the acne should be approximately 75% resolved with whatever primary treatment is being used (e.g., oral antibiotics or topical treatments) before using a peel. In addition, SA is probably the chemical of choice for acne rosacea.

#### **CONTRAINDICATIONS**

#### **Absolute**

- Concurrent or recent (within 6 months) isotretinoin (Accutane) therapy. It is best to obtain a release from the prescribing physician before performing a chemical peel.
- Concurrent radiation therapy.
- Allergies or hypersensitivities to agents used for chemical peels.
- Presence of melanoma or squamous cell or basal cell carcinoma in the region to be treated (if diagnosis is uncertain, obtain a biopsy first).
- Hemangiomas and nevus flammeus do not respond to chemical peels.
- Alcoholism (heavy alcohol use will impair healing, making it futile to do a peel).

TABLE 59-4         Protocols for Serial Glycolic Acid Peels (Performed 2 to 4 Weeks Apart)						
	ı ıı		Ш		Ш	
Indication	Conc. (%)	Time (min)	Conc. (%)	Time (min)	Conc. (%)	Time (min)
Acne	70	2	35	3	50–70	1–3
Melasma	70	3	35	4	50-70	2–4
Actinic keratoses	70	4	50	3	70	5–7
Fine wrinkles	70	5	50	4	70	4–8

Conc., concentration.

Modified from Gendler EC: Topical treatment of the aging face. Dermatol Clin 15:561-567, 1997.

#### **Relative**

- Concurrent hormone therapy (increased risk of postinflammatory hyperpigmentation).
- Herpes simplex virus. If there is a history of outbreaks, pretreat with an antiviral medication during the treatment period.
- Inflammatory lesions (e.g., herpes simplex, acute acne papule, cellulitis, severe seborrheic dermatitis) should be avoided during chemical peels. More peeling occurs in areas of inflammation, and hyperpigmentation can result. Dermatitis, areas of broken skin, and infection should be controlled before peels; otherwise the chemicals will penetrate more deeply.
- Smoking results in impaired healing and a greater risk of infection. Changes induced by peels will not counteract the damage to the skin from heavy smoking.
- Medium and deep chemical peels of the neck should be approached with extreme caution. In this area there is difficulty controlling the depth of the peel, thus increasing the risk of hypertrophic scarring.
- Although peels are not absolutely contraindicated, patients with as little as 1/32 Native American heritage may be at increased risk of persistent erythema and subsequent hyperpigmentation after a peel. This may be due in part to a reaction to chemicals.
- Patients with a history of allergy to parabens or perfumes may be at the same risk of excessive reaction and pigmentation.

Every precaution should be taken to prevent an allergic reaction to any agents, preservatives, or perfumes (see the Technique section). Oral and topical steroids for potential allergies should be considered. For patients with the potential for excessive reactions and subsequent hyperpigmentation, consider using a tyrosinase inhibitor (hydroquinone) early in the process (see the Complications section for a formula or the Suppliers section to order Bleacheze from Medical Center Pharmacy).

# **EQUIPMENT AND SUPPLIES**

- Water source in treatment room
- Eye wash or sterile saline
- Headband
- Towels
- Glass beaker for the peel solution
- Gentle facial cleanser
- 4 × 4 gauze pads
- Clock or timer
- Petroleum jelly
- Ultrasound gel
- Cotton-tipped applicators/swabs
- Acetone (for degreasing the skin)
- Hand-held fan for cooling (allows patient to maintain "control" by participating in comfort measure)

- Tepid water or 10% to 15% sodium bicarbonate solution for neutralizing
- Bowls for water
- Nonirritating moisturizer such as Aquaphor (available in drugstores)
- Sunblock to apply immediately after the peel
- Preprocedure photograph
- Postpeel instruction sheet
- Optional topical anesthetic for medium-depth peels (also see Chapter 10, Topical Anesthesia)
  - Lidocaine 2.5% and prilocaine 2.5% (EMLA) mixture
  - Lidocaine 4% (ELA-Max)
  - Lidocaine 7%/tetracaine 7%/benzocaine 20% cream (will need to be compounded)
  - BLT ointment (benzocaine 10%, lidocaine 20%, tetracaine 4%)
  - Quadri-caine (compounded)\*
  - Quadri-caine VC (with vasoconstrictor)

# **Superficial Peels**

Kits are available for superficial chemical peels, ranging in price from \$4 to \$10 per peel. The patient is charged from \$65 to \$100 per peel. Treatment for photodamage usually obtains optimal benefit after four to six peels, each 1 month apart.

- TCA 10% to 20%
- SA 20% to 30%
- AHAs 20% to 70% (e.g., glycolic, lactic, citric, malic, mandelic, tartaric)

**NOTE:** Although lower pH (i.e., pH < 2) GA solutions (50% to 70%) create more necrosis, there is no evidence that this leads to a more favorable peel. Additional necrosis produces additional crusting, making it more obvious that the patient has had a procedure performed as well as increasing the risk of complications. Therefore, partially buffered or neutralized GA solutions (i.e., pH > 2) are recommended.

#### Superficial to Medium-Depth Peels

- TCA 20% to 30%
- A series of AHA or BHA peels (Table 59-4)

# **Medium-Depth Peels**

• TCA 50% or TCA 35% plus initial keratolytics

<sup>\*</sup>Quadri-caine enhanced cream is a combination of four anesthetics formulated in a topical cream base containing a penetration enhancer (n-decyl methyl sulfoxide 0.25%). Each gram contains 100 mg of lidocaine USP, 50 mg of tetracaine USP, 50 mg of prilocaine hydrochloride, and 10 mg of bupivacaine hydrochloride.

**NOTE:** For patient safety and standardization, TCA should be compounded by a weight-to-volume method (i.e., 15% TCA is made by diluting 15 g of TCA crystals in distilled water up to a total volume of 100 mL).

# PREPROCEDURE PATIENT PREPARATION

Obtain informed consent from the patient before treatment (see sample consent form online at www.expertconsult.com).

In many cases patients will be asked to pretreat the skin with topical retinoids for 3 to 5 weeks before the peel. Benefits of pretreatment include the fact that it accelerates epidermal turnover, which will reduce healing time. If the topical retinoids cause bothersome or severe desquamation, they should be discontinued for several days and then resumed on alternate days.

For superficial and most medium-depth peels, patients can be informed that after the face is cleansed and prepared, applying the chemicals to produce the peel takes very little time, usually less than 1 minute (see Technique section). However, deep peels may require several hours, allowing time to make the patient comfortable, prepare the face, apply the chemical, complete the peel, and permit patient recovery if an antianxiety medication, pain management, or any type of anesthesia was used during the peel.

It is very important to know Fitzpatrick skin types before doing peels (see Chapter 46, Introduction to Aesthetic Medicine). Be aware that anyone of Native American heritage will be much more sensitive. Anyone with allergies to parabens, perfumes, or other skin preparations needs to inform the clinician so that precautions can be used. He or she needs to receive a patient teaching guide and must inform the clinician of any other possible contraindication. (See the sample patient education handouts available online at www.expertconsult.com.)

For superficial peels, patients may experience a stinging or burning sensation during application of the peel. This increases for 2 minutes after application, reaches a peak at 3 minutes, then dissipates over the following few minutes, resulting in a feeling similar to a sunburn. The chemicals themselves cause superficial anesthesia, and patients may find this information psychologically reassuring. In addition, patients usually report a slight tightness and smoothness of the skin immediately after superficial peels.

Within several days, some patients experience slight skin crusting, swelling, and possibly purpura in the lower eyelid areas, which generally resolve over the next 24 to 72 hours depending on the chemical used and the patient's skin type. Erythema almost always resolves in a few weeks.

Whenever the skin is peeled or wounded, there is a risk of scarring and infection. Also, pigmentary augmentation is both a short-term risk (it almost always resolves) and a long-term, permanent risk. The deeper the peel, the higher the risk of all of these side effects and complications.

Superficial peels very rarely cause complications; medium and deep peels are higher risks.

Patients should be aware that their postoperative appearance may be frightening, especially after medium or deep peels. This is rare for superficial peels. Patients should use hypoallergenic, non-scented, complete sunblock (SPF 30 or greater).

For superficial peels, the patient can wear makeup the day of the peel. It will be removed in the clinician's office. Topical retinoids should be stopped 3 days before the procedure. For medium and deep peels, the skin should be washed the evening before the procedure to remove all cosmetics and cleansed again in the office before applying the peeling agent.

**NOTE:** Disappointment with a chemical peel is most often the result of unrealistically high expectations on either the clinician's or patient's part. Patients should be given a patient teaching guide and made aware that superficial peels yield only modest clinical effects. After multiple peels, patients should be able to better appreciate the

benefits. Patients should also be reminded that the effect of a medium-depth peel is not comparable to a face lift. Professional-strength peels increase the effectiveness of GA or other AHA solutions that are used later at home by the patient.

### **TECHNIQUE**

For a sample documentation form, see Figure 59-2.

# Superficial Peels

- 1. Choose the proper mixture or concentration for the patient. AHA 20% to 70%, BHA (i.e., SA) 20% to 30%, or TCA 10% to 20% causes detachment of keratinocytes at the lower concentrations and epidermolysis at the higher concentrations.
- 2. Cleanse skin of residual debris, makeup, and body surface oils with alcohol or, preferably, acetone.
- 3. Using cotton-tipped applicators, apply a thin coat of petroleum jelly at the lash line, taking care to protect the medial and lateral canthi of the eyes, the mouth corners, and the edges of the nose (i.e., nasoalar junction; Fig. 59-3A through C). These are typically dry areas of the face and therefore need protection. Any inflamed lesion, such as an active acne lesion, should be avoided. Ask the patient if there are any other dry areas of the face that need protection from the peel. Patients usually know which areas of their nose and face are the driest.
- 4. After cleansing and applying protectant jelly, eye patches are placed to prevent accidental eye damage (Fig. 59-3D).
- 5. Starting on the forehead, apply the acid mixture evenly to the entire face, being careful not to pass your hand directly over the patient's eyes. Gentle stretching of the skin will allow the fluid to coat the depths of wrinkles evenly (Fig. 59-3E and F). In general, facial peels do not need to go beyond, but should generally be feathered just below, the jaw line and the fluid should not be applied closer than a couple of millimeters to the eyelid margin. Feather the solution into the hairline and along the chin to prevent a line of demarcation between the treated and untreated areas. If desired, the solution can also be used to extend the peel to the chest, neck, arms, and hands.
- 6. Allow the mixture to remain in place for the appropriate time (usually 3 to 5 minutes; Fig. 59-3G). Use a timer or a clock, but even more important, assess the patient and skin; do not rely on the timer alone. If there are any areas showing increased penetration, intense redness, or pain ("hot spots"), they can be neutralized with a cotton-tipped applicator dipped in ultrasound gel. The gel does not run like water, so it dilutes the acid effect on the area and decreases discomfort.
- Neutralize and gently blot the treated areas with either water or sodium bicarbonate solution unless the acid you are using is selflimiting and does not require neutralizing, such as SA or Jessner solution.
- 8. A hypoallergenic, nonscented moisturizer (e.g., Aquaphor) and complete sunblock should be applied immediately after the peel (Fig. 59-3H).

#### **Superficial to Medium-Depth Peels**

- 1. As for superficial peels, choose the proper mixture technique to obtain a superficial to medium-depth peel. A single agent can be used (TCA 20% to 30%) or superficial peels may be repeated every 2 to 4 weeks for a deeper peel effect or until the desired results are obtained. For AHAs or TCA, three or four treatments may be adequate (see Table 59-4); however, often six to eight SA peels are performed. In most cases, the best results are obtained if the patient waits 1 month between peels.
- 2. If TCA 20% to 30% is chosen, the skin to be peeled must first be dekeratinized to ensure uniform TCA penetration. AHA or SA superficial peels applied in the office a few days before the TCA procedure can be used for this purpose. Dekeratinization

can also be performed by the patient before arrival by applying topical retinoids to the skin surface daily for 3 to 5 weeks.

- Although anesthesia is not necessary, intravenous conscious sedation or topical anesthesia (see earlier discussion) may be used.
- Protect the necessary areas of the face with petroleum jelly in the same manner as for superficial peels.
- 5. Using a cotton-tipped applicator with the tip wrung out well to avoid dripping or splashing, apply the TCA to the entire face. It should be applied evenly to produce a smooth, white surface. Greater penetration in certain areas may be achieved by rubbing the applicator vigorously. Gently stretching the skin will allow the fluid to coat the depths of wrinkles evenly. The peel should not be extended below the jaw line. Desired areas of the hands and arms may also be treated.
- 6. Treatments may be repeated, if necessary, in 1- to 3-month intervals to achieve the desired effect.

# **Medium-Depth Peels**

Pretreatment with 0.1% tretinoin (Retin-A) daily for at least 2 weeks will enhance wound healing from medium-depth peels.

# Using a Combination of 70% Glycolic Acid and 35% Trichloroacetic Acid

- 1. After protecting areas of the face with petroleum jelly in the same manner as for superficial peels, apply a 70% GA mixture to the entire face.
- 2. Allow the mixture to remain in place for 2 minutes. A fan in the room may ease patient discomfort from the stinging associated with the peel.
- 3. Wash with water.
- Optional but effective: Apply a topical anesthetic for 30 minutes without occlusion.

**NOTE:** A study comparing two topical anesthetics (EMLA and ELA-Max) with each other and with a placebo found a statistically significant decrease in pain with both topical anesthetics and no difference in efficacy between the two anesthetics. Neither anesthetic affected the depth of penetration of the peel. Other topical anesthetics can be used based on clinician preference.

5. Remove the topical anesthetic and apply 35% TCA to the entire face as previously described.

Figure 59-3 Steps in a skin peel procedure (A–H). In this case, the Illuminize Peel followed by TNS Ceramide treatment (SkinMedica, Inc., Carlsbad, Calif) were used. See text for a description of each step. (Courtesy of John L. Pfenninger, MD/The Medical Procedures Center, PC, Midland, Mich.)

- 6. If successful and there are no complications, this technique can be extended to the hands, arms, and chest during the next peel. Depending on the chemical used, be aware of toxicity levels when treating multiple zones and larger surface areas.
- A cool compress applied to the area after a peel may ease patient discomfort.

# **Using Trichloroacetic Acid 50%**

The technique for a superficial to medium-depth peel with TCA 50% is the same as that noted for the combination 70% GA/35% TCA peel in the previous section.

# **COMPLICATIONS**

Persistent hyperpigmentation is a slight risk, but it is often adequately treated with a tyrosinase inhibitor (hydroquinone, often combined with steroids). One published formula combines 30 g of parabensfree corticosteroid cream, 15 g of 4% hydroquinone, and 20 g of Retin-A 0.1% into a cream to be applied starting 2 weeks after the procedure if hyperpigmentation is developing. Another option is Bleacheze (see the Suppliers section).

The use of oral corticosteroids for 2 weeks after the procedure, followed by a steroid cream, may prevent persistent hyperpigmentation in those at risk or with a history of previous hyperpigmentation.

#### POSTPROCEDURE PATIENT EDUCATION

For superficial peels, the effect is maximal at 48 hours, so the patient should attempt to avoid the sun completely for at least 3 days. If going outside is unavoidable during this time, the patient must use a sunscreen and wear a broad-brimmed hat and large sunglasses. The skin is most vulnerable to damage during this time and sun exposure can cause many problems, including swelling, a deepening of the peel, postinflammatory hyperpigmentation, and potential scarring.

Actual peeling usually begins 2 days after the treatment and can last for up to 7 days. Most patients peel in the central part of the face more heavily than peripherally, and only lightly on the forehead. Some patients peel in fine sheets, but most peel in flakes.

As stated previously, immediately after a superficial peel patients usually report a slight tightness, much like the feeling of a sunburn. A smoothness to the skin is felt and some patients may experience slight skin crusting. Occasionally, swelling occurs, as well as purpura in the lower eyelid areas. These symptoms resolve within a few days. The deeper the peel, the more likely the patient will have these side effects, and the longer they will last.

The effect of a medium-depth peel is maximal at 48 hours. Crusting and some swelling are to be expected and usually subside within the first week. Use of continuous lubrication and sunblock is essential to protect the new skin. If a home care skin regimen is not implemented and maintained, the result of the peel will likely wane by the third month after the procedure.

Aspirin and nonsteroidal anti-inflammatory drugs work very well for postpeel discomfort. A prescription for a mild pain medication may relieve any tingling or throbbing.

In about 7 to 10 days, new skin will be apparent and the patient should be healed sufficiently to return to normal activities. Patients should continue to protect their skin and avoid being in the sun without protection for several months.

After all peels, sunburn may occur at lower doses of sunlight and lead to hyperpigmentation or hypopigmentation. Preservatives, scents, or the chemicals used may also provoke a sensitivity reaction and cause persistent erythema; therefore, a hypoallergenic, non-scented, complete sunblock (SPF 20 or greater) for sensitive skin should be used. Even after healing, the postpeel skin is thinner and more susceptible to sun damage and sunburn. The patient should make a habit of wearing a broad-brimmed hat and large sunglasses, as well as using a complete sunblock every day, and should avoid direct sunlight as much as possible.

Thinner or irritated skin is also more susceptible to desiccation. Thus, a moisturizer should be applied daily.

### **PATIENT EDUCATION GUIDES**

See the sample patient education handouts online at www. expertconsult.com.

# **CPT/BILLING CODES**

15788 Chemical peel, facial; epidermal

15789 Chemical peel, facial; dermal

15792 Chemical peel, nonfacial; epidermal

15793 Chemical peel, nonfacial; dermal

### **ICD-9-CM DIAGNOSTIC CODES**

Although most insurers consider chemical peels a cosmetic procedure, occasionally they reimburse for treatment of acne, actinic keratoses, or acne rosacea.

695.3 Acne rosacea

702.0 Actinic keratosis

706.1 Acne

709.00 Dyschromia, unspecified

709.09 Lentigo

709.09 Melasma

709.2 Disfigurement because of scar

709.3 Senile dermatosis

#### **ACKNOWLEDGMENT**

The editors wish to recognize the many contributions by Grant C. Fowler, MD, and Stephen F. Ramirez, MD, to this chapter in the previous edition of this text.

# PHOTODYNAMIC THERAPY

Greta McLaren

The history of photodynamic therapy (PDT) dates back to the early 1900s. Various chemicals, acting as photosensitizers, were found to have cytotoxic effects on specific types of cells after absorption into the cell when followed by activation with light in the presence of oxygen. The principle of PDT is currently used medically to treat various dermatologic conditions, connective tissue disorders, and malignancies. This chapter reviews the various dermatologic conditions, both medical and cosmetic, that can be treated in the office setting using topical PDT. Both U.S. Food and Drug Administration (FDA)—approved applications as well as "off-label" applications are discussed.

PDT using the topical photosensitizer 5-aminolevulinic acid (ALA-PDT) as a procedure to treat various dermatologic conditions has been gaining popularity over the past decade among dermatologists and primary care physicians alike. The procedure received FDA approval in 1999 for the treatment of minimally to moderately thick actinic keratoses of the face and scalp. However, multiple off-label uses have been investigated and found to be safe and effective. Some of the more common off-label treatment protocols that can be performed in the office setting include the treatment of acne, photodamage, sebaceous gland hyperplasia, and hidradenitis suppurativa. Extensive research regarding the "off-label" use of ALA-PDT in the treatment of nonmelanoma skin cancers, including basal cell carcinoma and Bowen's disease, has been published. However, these topics are not covered in this chapter. Please refer to the Bibliography for more information on these subjects (e.g., Gilbert, 2007).

The most common form of ALA used by physicians in the United States is 20% 5-ALA (Levulan Kerastick; Dusa Pharmaceuticals, Inc., Wilmington, Mass). This photosensitizing chemical has the unique property of being absorbed by the outer layer of the skin and being taken up selectively by cells undergoing rapid turnover. As a result, this procedure allows for the targeting of rapidly reproducing, unhealthy, sun-damaged, precancerous, and cancerous skin cells.

The mechanism by which ALA-PDT works is as follows: once applied to the skin and allowed to incubate and be absorbed, ALA is converted to a potent photosensitizer (PS), protoporphyrin IX (PpIX). When exposed to oxygen and light of various wavelengths, PpIX reacts to produce a cytotoxic effect (singlet oxygen) on the targeted cells. The absorption peaks for PpIX show a maximum peak at 409 nm, with lesser peaks at 509, 544, 584, and 635 nm (Fig. 60-1). Higher fluencies (light energy) are needed for the lesser peaks, although the deeper penetration at the longer wavelengths may have an added benefit.

 $O_2 + PS + light \rightarrow singlet oxygen (which destroys the target)$ 

ALA-PDT used off label in the treatment of acne vulgaris works in two ways: (1) destruction of *Propionibacterium acnes*, the bacterium associated with the disorder; and (2) shrinkage of the oil glands with less production of oil as a result. The procedure is considered an alternative to isotretinoin (Accutane), with results in some studies lasting for up to 2 years.

In the presence of ALA, *P. acnes* makes a large amount of photosensitive porphyrins, increasing its photosensitivity. The pilosebaceous unit itself selectively accumulates the photosensitizer, PpIX. Light application again produces a chemical reaction that in turn kills the bacteria and also causes involution of the sebaceous gland.

A second PDT photosensitizer, *methyl aminolevulinate* (Metvix, Galderma Laboratories, Paris; and PhotoCure AS, Oslo), has been FDA approved as second-line therapy for the treatment of nonhyperkeratotic actinic keratoses of the face and scalp not amenable to conventional therapy. Despite FDA approval, however, Metvix has not yet been launched in the U.S. market.

Lasers and light sources capable of emitting wavelengths of light that correspond to the absorption peaks for PpIX (see Fig. 60-1) are possible sources for activation of ALA. The activating light source for ALA approved in the FDA protocol for the ALA-PDT procedure is the BLU-U, a 417-nm wavelength light manufactured by Dusa Pharmaceuticals. Multiple other light and laser sources noted under the "Equipment" section of this chapter have been found to be effective in activating ALA. Devices such as intense pulsed light (IPL) or pulsed-dye laser (PDL) can be synergistic in that not only are they capable of activating ALA, they are able to target other chromophores such as hemoglobin or melanin. As a result, these devices can simultaneously activate ALA and treat telangiectases and solar lentigines, thereby enhancing the cosmetic result for photodamaged skin. This procedure using a PDL or IPL source is often referred to as photorejuvenation with ALA.

# **INDICATIONS**

# **FDA Approved**

Actinic keratoses, mild to moderate thickness.

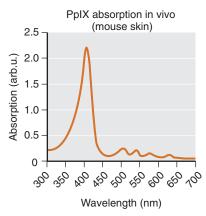

# Off-Label Use

- Acne vulgaris
- Acne rosacea
- Cosmetic photorejuvenation
- Sebaceous hyperplasia
- Hidradenitis suppurativa
- Nonmelanoma skin cancers
- Actinic cheilitis
- Warts

#### **CONTRAINDICATIONS**

### **Absolute**

- Pregnancy
- Breast-feeding (not studied)
- Planned sun exposure within 48 hours
- Isotretinoin (Accutane) use within the previous 6 months

**Figure 60-1** The absorption peaks for protoporphyrin IX (PpIX). (Courtesy of Dusa Pharmaceuticals, Inc., Wilmington, Mass.)

#### Relative

- Seizure disorder
- Diabetes
- Photosensitizing drug use
- Tobacco use

# **EQUIPMENT**

- Acetone and 4 × 4 gauze for skin preparation
- Microdermabrasion machine (optional)
- 20% 5-ALA (Levulan Kerastick)
- BLU-U (417 nm), ClearLight (405 to 420 nm; Lumenis, Ltd., Yokneam, Israel), Omnilux Blue Light (415 nm; Photo Therapeutics, Inc., Carlsbad, Calif), PDL (585 or 595 nm), broad-band light source or IPL (410 to 1200 nm)
- Zimmer chiller (optional)

# **PATIENT SELECTION AND PRECAUTIONS**

• Photodynamic therapy with ALA can be used on all skin types, Fitzpatrick I through VI, if indicated, using one of the previously noted light devices. Photorejuvenation using an IPL or PDL should be reserved for patients with skin types I through IV only. Patients with darker skin types (Fitzpatrick IV and above) are more susceptible to postinflammatory hyperpigmentation (PIH) after this procedure. These patients should be well informed of the potential risk of PIH before undergoing the procedure. For the first PDT treatment in skin types IV and above, a shorter incubation time should be considered. The incubation time for subsequent treatments may be gradually increased in 15-minute increments if tolerated (Table 60-1). It is prudent in these patients to take prophylactic measures by prescribing a skin-lightening agent such

- as hydroquinone 4% gel or cream 2 weeks before and up to 4 weeks after the procedure when treating skin types IV and above.
- The side effects and potential downtime with this procedure vary significantly from patient to patient. Some of the more common side effects are erythema, swelling, peeling, crusting, dryness, and discomfort. As a general rule, the amount of target tissue present, such as the prevalence of actinic keratoses or severity of acne, along with the length of the incubation period will determine the amount of downtime and side effects.
- Retinoid use before the procedure may enhance the results but will
  also increase the downtime. For better predictability of downtime
  and side effects, retinoids can be discontinued 1 to 2 weeks before
  the procedure, unless the enhanced effect, with its potential
  increased severity of downtime, is desired and discussed with the
  patient during the consultation.
- ALA-PDT should not be performed on patients who have used isotretinoin (Accutane) within the previous 6 months.
- The use of photosensitizing drugs, including tetracyclines, must be taken into consideration when performing this procedure. It is acceptable to continue the medication during the treatments; however, the incubation time of ALA is decreased by 15 minutes on the initial treatment to determine if increased side effects due to photosensitivity are likely to occur.
- The discomfort and nerve irritation that may occur with ALA-PDT may stimulate a herpes simplex virus recurrence in patients with a history of cold sores. Antivirals should be used prophylactically to prevent this potential side effect in such patients.

# PATIENT EDUCATION AND POST-TREATMENT GUIDELINES

Because of the potential severity of side effects and reactions to this procedure, an initial consultation with the patient by a physician with a full explanation of the potential risks, downtime, and side effects is recommended. Once ALA is applied and absorbed in the skin, it may remain reactive to sunlight for the next 24 to 48 hours, regardless of cleansing after the application. It is therefore imperative that patients understand the need to *avoid sunlight*, both direct and indirect, for a minimum of 48 hours after the procedure. An educational handout and informed consent should be reviewed with the patient during the initial consultation.

#### **PROCEDURE**

- 1. Baseline photographs are always helpful.
- 2. Review consent form and post-treatment guidelines with the patient.
- Review the history to note any contraindications or use of photosensitizing drugs.
- 4. Note any cold sore risk and prescribe antivirals if indicated.

TABLE 60-1 Levulan Incubation Time for ALA-PDT Treatment					
Area	Treatment Number	Fitzpatrick Skin Type	Disease Severity	Occlusion	Time (in minutes)
Face/scalp	First	I–III	Mild to moderate	No	60
	Second-Fifth	I–III	Same as above	No	60–90*
	First	I–III	Moderate to severe	No	30
	Second-Fifth	I–III	Same as above	No	45-60*
	First-Fifth	IV-VII	All	No	30-45
Chest, back, arms or legs	First-Fifth	I–III	Mild to moderate	Yes	120
	First-Fifth	I–III	Moderate to severe	Yes	90-120
Chest, back	First-Fifth	IV-V	All	Yes	60–90
	First–Fifth	VI	All	Yes	60

<sup>\*</sup>Incubation time may be gradually increased with subsequent treatments if the patient's reaction is well tolerated

- 5. Cleanse and prepare the skin with either a vigorous acetone scrub or microdermabrasion.
- 6. Crush the Levulan Kerastick according to directions and shake the solution for 3 minutes.
- 7. Protect the patient's eyes and mouth with petrolatum ointment or gauze and apply the Levulan solution to the treatment area (face, neck, chest, back, arms, hands, or legs). Areas with more severe disease may be treated with a second coat of Levulan.
- 8. Incubate to allow for sufficient absorption of the Levulan depending on area, disease severity, and skin type (see Table 60-1).
- 9. Areas other than the face and neck, such as chest, back, hands, arms, and legs, require longer incubation times for sufficient absorption of the Levulan. If treating these areas, occluding the area with cellophane (kitchen plastic wrap) and tape will enhance the absorption and decrease the incubation time required (see Table 60-1).
- 10. When significant acne and or photodamage is present or if the patient has a darker skin type and is at risk for PIH, consider a shorter initial incubation time. Gradually increase incubation times with subsequent treatments, depending on tolerance. Do not exceed a 30-minute incubation time in Fitzpatrick skin type VI because of the increased risk of PIH in these patients (see Table 60-1).
- 11. Wash the treated area with a gentle cleanser and water after incubation, before starting the light treatment.
- 12. Activate the Levulan by exposing the treated area to a light source. Narrow-band blue light, IPL, PDL, and light-emitting diode light that falls within the required wavelength absorption spectrum for PpIX (see Fig. 60-1) are all possible sources for activation of Levulan. The operator should use the chosen device in accordance with the individual device's operating protocol. If using the BLU-U light alone, the exposure time is approximately 15 minutes. The recommended energy for the Omnilux 415-nm light, according to the manufacturer, is 48 J/cm<sup>2</sup> for 20 minutes. However, this energy setting can cause significant discomfort, so start with a setting of 24 J/cm<sup>2</sup> for 20 minutes. Energy settings can always be increased. For significant photodamage, actinic keratoses, or deep cystic acne, use IPL at 25 to 45 J/cm<sup>2</sup>, depending on the skin type and cooling mechanism, followed by additional exposure using blue light (410 to 417 nm) at 10 to 48 J/cm<sup>2</sup> for 3 to 8 minutes, depending on the energy settings used.
- 13. Apply a gentle moisturizer or Aquaphor.
- 14. Inform the patient that the redness and swelling will likely intensify over the next 48 hours. The patient should use a hat or umbrella and sunscreen to guard against any sun exposure for the next 48 hours.
- 15. Patients appreciate a follow-up by phone or office visit in 24 to 72 hours.
- 16. To help prevent PIH, prescribe a lightening agent such as hydroquinone 4% cream for darker skin types (IV to VI) once the skin is fully recovered.
- 17. When IPL with ALA is used for sebaceous gland hyperplasia, at a 7- to 10-day follow-up, hyfrecate the majority of the lesions still present. After two to three treatments with ALA-PDT, there is a significant reduction in the number of newly occurring lesions.

#### **COMPLICATIONS**

- PIH is a potential complication of this procedure. If this occurs, prescribe a combination cream of hydroquinone 4%, tretinoin 0.05%, and fluocinolone acetonide 0.01% to be used once or twice daily for up to 8 weeks. Microdermabrasion every 2 weeks may also be added.
- Sun exposure in the first 48 hours may result in blistering, severe discomfort, and peeling. Cold compresses, pain medication, Aqua-

**Figure 60-2 A,** Photodamage before treatment. **B,** Photodamage after three photodynamic therapy treatments with intense pulsed light and BLU-U.

- phor, and frequent follow-up visits to monitor for infection are recommended.
- Infection is rare but can occur. If impetigo occurs, mupirocin (Bactroban) topical ointment or cephalexin 500 mg twice daily may be prescribed for 7 to 10 days. If herpes simplex virus infection occurs, antivirals such as acyclovir should be prescribed.
- Also see some of the common after-effects noted previously.

#### POSTPROCEDURE MANAGEMENT

Avoiding sun exposure and keeping the treated area moist are essential. Aquaphor is a preferred healing ointment. To soften any significant crusting, apply wet gauze soaked in a solution of one teaspoon of vinegar to one cup of water. This may be applied for 10 minutes three times daily.

#### **RESULTS**

With three to five photorejuvenation treatments with ALA-PDT (60-minute incubation time) in combination with IPL followed by BLU-U for 3 minutes (Fig. 60-2A and B); or with three to five acne treatments with ALA-PDT (60-minute incubation time) and BLU-U exposure alone for 15 minutes (Figs. 60-3 and 60-4), the patient satisfaction rate is very good.

Figure 60-3 Acne before treatment.

Figure 60-4 Acne after three photodynamic therapy treatments with BLU-U.

# **PATIENT EDUCATION GUIDES**

See the patient education and patient consent forms available online at www.expertconsult.com.

# **BILLING AND CODING**

Limited reimbursement for the FDA-approved treatment of actinic keratoses is available through some insurance companies. The majority of the off-label uses of ALA-PDT are considered cosmetic and are unlikely to be covered by insurance.

- For treatment of actinic keratoses, use the CPT code 17004 (destruction premalignant lesions, 15 or more).
- For acne, the ICD-9 code is 706.1 (photodynamic therapy by external application of light to destroy premalignant and/or malignant lesions of the skin and adjacent mucosa, each phototherapy exposure session).
- Use J code 7308 for amino-levulinic acid.

For support in documentation and billing and current CPT codes, Dusa Pharmaceuticals has a reimbursement and coding support center:

# **CELLULITE TREATMENTS**

Yves Hébert

Cellulite is a condition that occurs mostly in postpubescent women in which the skin of the lower limbs, abdomen, and pelvic region becomes dimpled. The term was first used in the 1920s in France and began appearing in English-language publications in the late 1960s

Descriptive names for cellulite include orange-peel syndrome and cottage cheese skin. Synonyms include adiposis edematosa, dermopanniculosis deformans, sclerotic-fibrous-edematous panniculopathy, and gynoid lipodystrophy.

# **ANATOMY OF CELLULITE**

Fat is stored in *fat cells* that lie between the skin and the muscle underneath.

The fat cells are grouped together into large collections that are separated by fibrous strands, or *septa* (Fig. 61-1). These septa run between the muscle and the skin. As the fat cells expand with weight gain, the gap between muscle and skin expands, but unfortunately the septa cannot stretch. This results in the *dimpling* characteristic of cellulite.

The layers of fat are separated into three zones by two planes of connective tissue (Fig. 61-2):

- The *upper zone*, where the fat cell chambers stand vertically separated by radially running septa of connective tissue
- The middle and lower zones, where the squat fat chambers and the septa of connective tissue run tangentially to the fascia

# **CLASSIFICATION**

Cellulite is classified using the Nurnberger-Muller scale:

- Stage 0: Skin surface is smooth while standing or lying, but *folds* or *furrows* appear when the skin is pinched.
- Stage 1: Skin surface is smooth while standing or lying, but dimples appear when the skin is pinched.
- Stage 2: Cellulite is present when standing, but disappears when lying.
- Stage 3: Cellulite is present regardless of position.

# **PATHOPHYSIOLOGY**

The overlying skin begins to bulge as excess fat is stored in the subcutaneous fat cells. With time, the accumulating fatty deposits compress the circulation and create congestion. As congestion increases, fluid and sugars leak out of the vessels to form complex sugar chains that draw even more fluid out of the vasculature through osmolarity. Fat cells begin to organize within fibrous nets to become fatty lobules. Gradually, these fatty lobules invade the skin's dermis and the fibrous nets become more rigid, finally creating skin dimpling ("peau d'orange").

# **CAUSES OF CELLULITE**

Currently, the causes of cellulite are poorly understood. It is widely accepted that hormonal factors play a dominant role:

- Estrogens seem to initiate and aggravate cellulite
- Insulin, catecholamines, epinephrine and norepinephrine, thyroid hormones, and prolactin participate in the development of cellulite

Disorders of water metabolism, abnormal hyperpolymerization of the connective tissue, and chronic venous insufficiency are also involved in the pathogenesis of cellulite.

Many predisposing factors are identifiable:

- Sex
- Race
- Phenotype
- Lifestyle
- Smoking status
- Predisposition to circulatory insufficiency
- Abnormal distribution of subcutaneous fat (apple or pear shape)
- Obesity

# TREATMENT OF CELLULITE

# **Detoxification Diet**

The detoxification diet has been shown to affect the development and amount of cellulite, but it is not a definite cure for cellulite. This diet recommends *less* alcohol, caffeine, refined food (salt), saturated fat, refined carbohydrates, smoking, diet pills, sleeping pills, laxatives, and diuretics, and *more* fresh vegetables and fruits, water, fibers and whole-grain foods, essential nutrients (calcium, potassium, vitamins B and C, glucosamine), and essential fatty acids. All patients wishing to improve the appearance of cellulite should adopt most of the recommendations of this diet but must understand that diet by itself is not a cure for cellulite.

#### **Exercise**

Exercise plays an important role in cellulite reduction and is one of the most effective and inexpensive measures for cellulite reduction. Exercise improves the following:

- Muscle tone
- Circulation
- Lymphatic drainage

Aerobic activity, yoga, Pilates, swimming, walking, biking, and stair climbing are excellent forms of exercise for patients with cellulite. Exercise is a fundamental part of the treatment of cellulite and should be strongly encouraged in all patients.

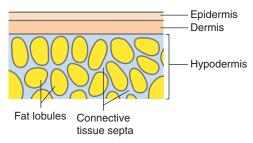

Figure 61-1 Skin and subcutaneous tissue with fat lobules and septa.

# **Physical and Mechanical Methods**

Numerous therapies have been attempted:

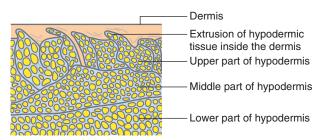

- Iontophoresis (transdermal transmission of medication using small electrical charges)
- Ultrasound (high-frequency sound waves)
- Thermotherapy (induced localized hyperthermia)
- Pressotherapy (pneumatic massaging in the direction of the circulation)
- Lymphatic drainage (massage technique to stimulate lymphatic flow)
- Electrolipophoresis (application of a low-frequency electric current)

However, no reports in the scientific literature have shown consistent results. They are possibly helpful in selected patients with lymphatic drainage deficiency.

# **Pharmacologic Agents**

Several drugs that act on fatty tissue have been tried as therapeutic agents. Certain drugs act on the fatty tissue, connective tissue, and the microcirculation. They can be used topically, systemically, or transdermally:

- Methylxanthines (theobromine, theophylline, aminophylline, caffeine), which act through phosphodiesterase inhibition
- Pentoxyphilline, which improves the microcirculation
- β-Adrenergic agonists (isoproterenol and epinephrine)
- α-Adrenergic agonists (yohimbine, piperoxan, phentolamine, dihydroergotamine)
- Methylxanthine enhancers (coenzyme A and the amino acid L-carnitine)
- Drugs with connective tissue activity (silicium and Centella asiatica)
- Microcirculation-active drugs (Indian chestnut, gingko biloba, and rutin)

Dark fibrous streaks (septa) separate fat lobules inside the hypodermis and fascia

Figure 61-2 Zones of connective tissue in the hypodermis.

None of these medications has been reported in the scientific literature as having a significant effect on cellulite. Some patients could benefit temporarily from an effect on microcirculation.

#### **Anticellulite Creams**

Anticellulite creams provide a temporary reduction in cellulite by plumping up the skin and creating a smoother texture. They do not remove the "orange-peel" cellulite appearance. The key ingredients in the creams have antioxidant and anti-inflammatory effects:

- Aminophylline: reduces the bumpy, dimpling effect of cellulite
- Retinol and α-hydroxy acids (AHAs): improve skin texture by exfoliation of dead cells
- Caffeine: reduces fat content in cells by blocking phosphodiesterase, an enzyme that inhibits fat breakdown.

These creams have an indirect effect on cellulite by improving the quality of the skin through skin rejuvenation.

# **Mesotherapy**

Originating in France in the 1950s, mesotherapy is still very controversial in North America. It is practiced extensively in Europe and South America. Small amounts of medications and vitamins are intradermally injected directly into cellulite-affected areas to increase circulation, to decrease fibrosis of the connective tissue, and to decrease fat cells.

#### Indications

- Spot and cellulite reduction
- Weight loss
- Skin rejuvenation

# Side Effects

- Redness and burning that may last for a few days
- Swelling and sensitivity around the treated area for several weeks

# Treatment Protocol

Ten to 15 weekly sessions are necessary to achieve visible results.

**NOTE:** While good reports have come from Europe and South America about the results of this treatment, products are not readily available in North America since the procedure is uncommon.

# Lipodissolve

Lipodissolve is a nonsurgical medical procedure that involves the injection of phosphatidylcholine (PPC) into the skin to dissolve fat. The treatment is meant to destroy fat cells, which are eliminated from the body through normal waste removal. The desired end result is precise body contouring in localized areas. PPC is a naturally occurring enzyme and is the main component of soy lecithin. Lecithin has been medically proven to have the ability to break down fat and reduce cholesterol. PPC has been used for fat removal and cellulite reduction by physicians for several years as a safe, noninvasive alternative to surgical procedures such as liposuction.

#### **Treatment Protocol**

- Multiple microinjections directly in the subcutaneous tissue
- One to three treatment sessions about 6 weeks apart

The procedure is still very controversial and possibly harmful if done by inexperienced providers because of risk of tissue necrosis. It should be used on selected patients only with localized pockets of fat tissue.

# **Devices and Technologies**

### Med Sculpt

See Figure 61-3A. Through a nonmechanical massage and a powerful ultrasound beam, the Med Sculpt system (Sound Surgical Technologies, Louisville, Colo) generates lipoclasis and stimulates the connective layers of the skin for a toned and smoother appearance to the treated areas (mechanical, thermal, and cavitational effects).

#### **PROTOCOL**

- Eight sessions twice a week with the vacuum-operated massage
- Four to six sessions at 3-week intervals with the hydrolipoclasia treatment (infiltration of physiologic solution before applying a strong ultrasound beam)
- Ten sessions twice a week of massage only

#### **CLINICAL BENEFITS**

- Compact loosening of the fatty tissue matrix
- Stimulation of lymphatic and venous circulation
- Redistribution of subcutaneous fat
- Moderate results on mild cases of cellulite

#### **Endermologie**

See Figure 61-3B. Endermologie (LPG Systems, Valence, France) is a temporary cellulite reduction technique. Mechanical rollers and suction provide intense massage to cellulite-affected areas by stimulating circulation to the affected zone. It is said to increase circulation by up to 200%, creating a smoother and toned effect to the cellulite problem areas.

#### **CLASSIC TREATMENT PROTOCOL**

- Thirty to 45 minutes per session, one to two times per week until the desired cellulite reduction has been achieved.
- An average of 15 to 18 treatments is required to achieve visible results, and more treatments are required to maintain the results.

**LIPOMASSAGE BY ENDERMOLOGIE.** This form of Endermologie delivers more intense treatments for faster results with newly designed rollers. Six treatment sessions are recommended.

**ENDERMOLOGIE EXPRESS.** Sessions are more vigorous and energetic, requiring subject participation. Soliciting the muscles with contraction–relaxation repetitions, the new protocols isolate fat layers and work them more intensively.

Figure 61-3 A, Med Sculpt (Sound Surgical Technologies). B, Endermologie (LPG Systems). C, TriActive Cellulite Workstation (Cynosure, Inc.). D, VelaShape (Syneron, Inc.). E, Accent<sup>XL</sup> (Alma Lasers, Ltd.). F, SmoothShapes XV system (Elemé Medical). (A, Courtesy of Sound Surgical Technologies, Louisville, Colo.)

**NOTE:** Enderomologie technology is very operator dependent and patients should inquire about the experience and the training of the technician operating the machine. Results are temporary, as with most of these technologies.

#### TriActive Cellulite Workstation

See Figure 61-3C. The TriActive Cellulite Workstation (Cynosure, Inc., Westford, Mass) provides a comfortable mechanical massage and rhythmic aspiration to distend the skin in various directions and enhance microcirculation, thereby increasing skin elasticity and improving lymphatic drainage. Six diode lasers penetrate tissues to stimulate fibroblasts for collagen production, yielding smoother, healthier-looking skin. The system can be used in combination with other therapies to enhance the outcomes of surgical and nonsurgical procedures such as liposuction and dermal fillers. This technology provides limited temporary action on superficial cellulite.

# VelaShape

See Figure 61-3D. The VelaShape (Syneron, Inc., Irvine, Calif) is a U.S. Food and Drug Administration—cleared system for circumferential reduction through four mechanisms of action:

- The vacuum induces vasodilation and allows deeper penetration of bipolar radiofrequency (RF).
- Massage trough roller movements soften tissues and assist in lymphatic drainage.
- Infrared light (IR) combined with vacuum provides strong, nonspecific dermal heating, leading to skin toning and firming through collagen stimulation.
- Optimized, controlled RF delivery results in greater depth of penetration and higher peak temperature in the subcutaneous tissue.

# TREATMENT PROTOCOL

- · Four to eight sessions using both applicators
  - Vsmooth for larger areas
  - Vcontour for smaller areas and localized action

#### **CLINICAL INDICATIONS**

- Circumferential reduction
- Cellulite reduction
- Body reshaping through cellulite treatment
- Postliposuction treatment through circumferential reduction
- Postpartum treatment through circumferential reduction

**NOTE:** The combination of massage, vacuum, and heat (IR and RF) provides interesting results, improving cellulite through skin tightening and circumferential reduction. Patients should be made aware of the short duration of the results and the importance of a maintenance program.

# **Accent**<sup>XL</sup>

See Figure 61-3E. The Accent<sup>XL</sup> (Alma Lasers, Ltd., Caesarea, Israel) is an upgradeable, multiapplication, multitechnology, RF-based platform that performs volumetric thermotherapy for the noninvasive treatment of wrinkles and rhytids. A dual-mode RF system tightens and recontours the skin using proprietary unipolar (for deep subcutaneous remodeling) and bipolar (for superficial skin tightening) RF energy, delivered with separate handpieces. Figures 61-4 and 61-5 show the results of treatment with the Accent<sup>XL</sup>.

**TREATMENT PROTOCOL.** Four to six sessions 3 to 4 weeks apart.

#### **CLINICAL INDICATIONS**

- Skin tightening and rejuvenation
- Cellulite reduction
- Body contouring
- Scar improvement

Figure 61-4 Before (A) and 2 weeks after (B) one Accent<sup>XL</sup> treatment using the unipolar handpiece. (Courtesy of Emilia del Pino, MD, and Ramon Rosado, MD, Mexico City.)

- Postliposuction touch-ups
- Acne improvement

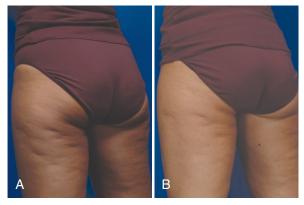

**NOTE:** The dual-mode RF system (bipolar and unipolar) improves the appearance of cellulite, but patients should be advised that results are temporary and need maintenance.

### SmoothShapes

See Figure 61-3F. The SmoothShapes XV system (Elemé Medical, Merrimarck, NH) effectively treats cellulite by improving the overall condition of enlarged fat cells and inflexible fibrous septae through a proprietary technology called Photomology, which is non-destructive. Photomology restores enlarged cells through a unique mechanism of action that combines dynamic laser and light energy with mechanical manipulation (vacuum and massage) to specifically target problem cellulite resulting in smoother looking skin.

The 915 nm (nanometer) wavelength penetrates well into the tissue and is preferentially absorbed by lipids, causing a thermal effect. The temperature inside the adipocytes is slightly elevated. Contoured rollers move liquefied lipids from the interstitial space to the lymphatic system for dynamic drainage.

**TREATMENT PROTOCOL.** Eight to 10 sessions on a weekly schedule.

**Figure 61-5** Before (**A**) and 4 weeks after (**B**) seven Accent<sup>XL</sup> treatments using the unipolar handpiece. (Courtesy of David McDaniel, MD, Assistant Professor of Clinical Dermatology and Plastic Surgery, Eastern Virginia Medical School, Norfolk, Va.)

# THE THREAD LIFT USING BARBED SUSPENSION SUTURES FOR FACIAL REJUVENATION

Vincent C. Giampapa • Hakan Usal • Oscar Ramirez

Surgeons and patients alike are constantly searching for methods of facial rejuvenation that can be performed with minimal tissue invasion, with the least amount of anesthesia, and with "no" downtime. This is the "holy grail" of aesthetic surgery. One of the latest procedures in this field is the barbed thread lift, although suture suspension during lifting has been successfully performed for over two decades. The original type of suture suspension for the midface and neck required an open or a semiopen procedure. Suture suspension worked because of the wide undermining and repositioning of the soft tissues in the elevated position, which was held over the long term by the sutures until scar formation allowed tissue reattachment in the new position. However, when suture suspension was applied in a percutaneous fashion, the general complaint was that the suture tended to act like a "cheese-cutting wire" that would eventually cut through the tissues and diminish the effect over a period of time. The reason this happened was that the sutures were smooth instead of barbed. The advent of the barbed suture represented a new concept in facial lifting because of the ability of barbed sutures to hold and support tissues along their entire length rather than just at the loop made by the smooth sutures. This mechanical advantage provided by the barbed suture permitted its use without the need for tissue undermining.

The barbed suture also makes it easy to insert in one direction and difficult to move in the opposite direction. Once the suture is introduced in the soft tissues, it can be lifted to a position in one direction and the barbs will theoretically prevent the tissues from drooping to their former, original position. Although in principle this made a lot of sense, the early configuration of the barbed sutures was not effective enough. Over time, surgeons modified and improved the configuration of the barbed sutures as well as the surgical principles evolved.

#### **HISTORY OF BARBED SUTURES**

In 1964, New Jersey physician J. H. Alcamo patented a roughened suture that offered resistance in one direction only. However, there is no reference to its clinical use. In 1984, Fukuda patented the surgical barbed suture.

The next important landmark was the work done by Russian cosmetic surgeon Marlene Sulamanidze, who, working with Georges Sulamanidze and Tatiana Paikidze from 1986 to 1998, studied a series of subdermal thread insertions using threads from 5 to 18 cm long. This is the first clinical report of the concept and technique of barbed sutures. They described the application of barbed sutures in the subcutaneous plane without undermining. They called their suture design *Aptos (antiptosis) threads*. These sutures were intro-

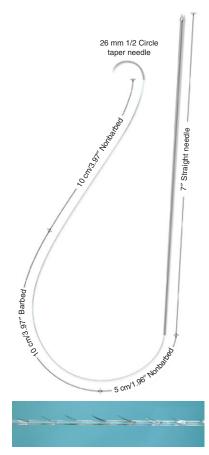

duced in the United Sates under the name Featherlift sutures. However, the Featherlift design did not gain U.S. Food and Drug Administration approval until June 2004.

In the United States in the late 1990s, Gregory Ruff invented what is now called the Contour Thread. The difference between the Featherlift and Contour Thread sutures is that the former is a bidirectional, free-floating device that does not require specific anchoring, whereas the latter is a unidirectional barbed suture with needles attached to both ends. The Featherlift requires a hollow cannula for insertion and is not anchored to a fixed structure. It is a self-anchoring device with one barbed segment used to "lift" the lower tissues while the upper barbed segment provides support in a higher position. The first-generation Contour Thread had a unidirectional barb configuration and one needle attached to each end. One long, straight needle is used to thread the suture into the tissues to be lifted (e.g., cheek) and the other end is used to anchor the thread in a fixed structure (e.g., temporal fascia). Subsequently, Leung and Ruff patented other variations and configurations of sutures, such as bidirectional barbed sutures with different types of needles and suture lengths.

#### **BIOMECHANICS OF BARBED SUTURES**

Not all barbed sutures are the same. The Aptos barbed sutures are made of 3-0 blue polypropylene with cogs that are relatively longer and thinner than the Contour Thread cogs (Fig. 62-1). The Contour Thread sutures are made of 2-0 clear polypropylene.

The Aptos thread is introduced using a hollow cannula of larger diameter than the suture, whereas the Contour Thread has attached needles of slightly larger diameter than the suture. Because the Aptos suture is inserted through a wider channel, this theoretically may make the cog engagement slightly looser. The Contour Thread needle also widens the channel through which the suture is placed. The flexible needle configuration of the Contour Thread allows the suture to be introduced in a zigzag fashion (Fig. 62-2), which in turn allows better anchoring of the barbs in the tissue. Biomechanical studies have also shown that the shorter the length of the barbs, the stronger their grip on tissues. The Aptos thread has longer barbs than the Contour Thread. Needle attachment at both ends, as well as the bidirectional barb configuration, gives the Contour Thread the additional versatility of permitting a change in direction at the end of the path to apply suture knots if needed or to anchor in a loop of the central, nonbarbed segment. The newest sutures feature a helicoidal distribution of cogs, offering an even better grip. A design still in development is an absorbable suture that can be used in semiopen or open methods of tissue lifting.

**Figure 62-1** The Contour Thread. *Bottom*, Magnified barbed section of thread.

As with all cosmetic surgery procedures, patient selection is the key initial decision in obtaining optimal results. The Contour Thread procedure fulfills the demands of cosmetic patients because it is a minimally invasive yet effective procedure. It offers significant improvement in facial rejuvenation with minimal downtime and potential complications.

#### **ANATOMY**

There are *four natural aging changes* one needs to consider when seeking to rejuvenate the midface. These were originally described by Hester and colleagues (2000) and include (1) gradual *ptosis of the cheek skin* below the inferior orbital rim with descent of the lax lower eyelid skin (this creates a skeletonized appearance with hollowness around the infraorbital area); (2) *descent of the malar fat pads* with

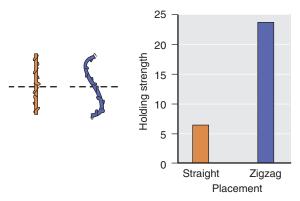

Figure 62-2 Optimized placement patterns.

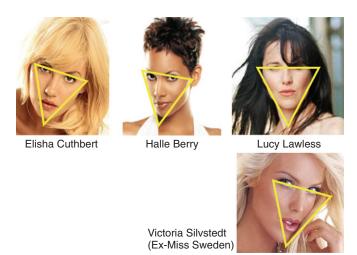

Figure 62-3 The "triangle of youth."

loss of malar prominence in projection; (3) a prominence and deepening of the tear trough area; and (4) a marked enhancement of the nasolabial fold. These anatomic areas have been called the triangle of youth (Fig. 62-3); a youthful facial appearance and contour can be retained by limiting the effects of aging in these areas.

#### **INDICATIONS AND USES**

- Mild to moderate facial laxity
- Midface laxity
- Neck laxity

The longevity (anywhere from 2 to 4 years) of the rejuvenation obtained depends on the patient's age and quality of facial anatomy. The best result is obtained in a younger individual who displays early signs of facial aging. Patients with strong skeletal support also have better results and greater longevity with the procedure. The poorest candidate is the older individual with severe sagging, redundant skin, and poor skeletal support.

#### **CONTRAINDICATIONS**

- Older individuals with severely sagging, redundant skin and poor skeletal support
- Uninformed patients with exaggerated expectations
- Patients who are unwilling to comply with a proper postoperative care program

The goal of midface rejuvenation centers around restoring the "triangle of youth," which consists of the malar eminence, nasolabial fold, corners of the mouth, and labiomandibular area (see Fig. 62-3). With the appropriate placement of Contour Threads, specific areas of the midface can be individually targeted for improvement. It is important to inform prospective patients that results using Contour Threads will not equal those obtained with an open facelift, either immediately or in the long term. The ideal patient is one with mild to moderate (class I to III) facial laxity. In particular, patients with laxity in the midface and neck area do very well (Fig. 62-4).

#### **EQUIPMENT AND SUPPLIES**

- 0.5% lidocaine with epinephrine
- Sodium bicarbonate to buffer the lidocaine
- 24-gauge, 4-inch spinal needle
- 27-gauge, 1½ -inch needle
- No. 15 scalpel blade and handle
- 4 × 4 gauze pads

(Midface, neck, brows)

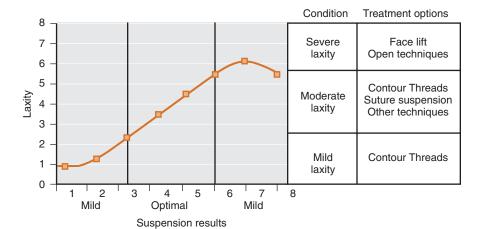

Figure 62-4 Patient selection factors.

- Alcohol wipes
- Lifting thread of choice (e.g., Contour Threads)
- Steri-Strips
- Elastic foam dressing

#### PREPROCEDURE PATIENT PREPARATION

No special preparation is needed before the patient comes to the office for the procedure. Standard consent forms are used.

#### **TECHNIQUE**

#### Midface Lift

- The patient is premedicated with oral diazepam (Valium) 5 mg, oxycodone/acetaminophen (Percocet) 5 mg, and Dramamine 10 mg 30 minutes before the procedure.
- 2. Mark the patient as shown in Figure 62-5.
- 3. Lidocaine 0.5% with epinephrine 1:200,000 (up to 100 mL) is mixed 10:1 with sodium bicarbonate (buffering lessens the stinging effect). This is injected into the incision sites on the

- temporal scalp as well as the proposed needle pathways with a 27-gauge needle and a 24-gauge, 4-inch spinal needle.
- 4. A small, 1- to 2-cm incision is made in a temporal hair-bearing area to introduce the Contour Threads (2-0 polypropylene suture) for the midface lift.
- 5. The Contour Threads are placed through the temporal incision and directed downward. This technique focuses on improving the four key anatomic areas to maximally restore the triangle of youth and provide a more youthful appearance. Each anatomic area is corrected using a specific thread for a specific purpose (see Fig. 62-5).
- 6. The placement of *thread no. 1* is designed to improve lateral orbital rim and infraorbital rim hollowness, which is a key sign of aging in the triangle of youth. To avoid palpation of the suture, the subcutaneous plane is gently pinched between the thumb and index fingers during suture placement.
- 7. Thread no. 2 restores the descent of the malar pad and improves the superior portion of the nasolabial fold. Over the malar eminence and below the zygomatic arch, the suture is placed deeper into the superficial muscular aponeurotic system (SMAS) level and slowly introduced with a weaving action before it exits with a slight curve.

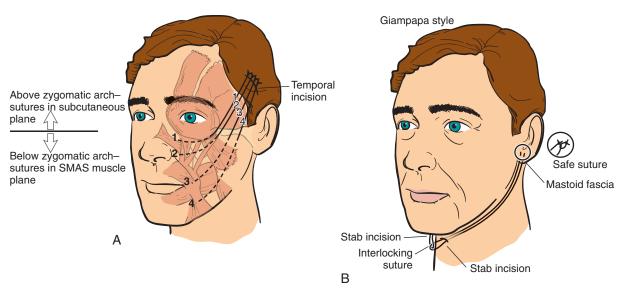

Figure 62-5 A, Basic suture placement for midface rejuvenation. (1) Infraorbital hollow and orbital rim depression; (2) malar eminence descent and superior portion of nasolabial fold; (3) ptosis of lateral commissure of mouth and inferior nasolabial fold; (4) labiomandibular fold; SMAS, superficial muscular aponeurotic system. B, Neck lift with interlocking suture (Giampapa style).

- 8. The no. 1 and no. 2 threads are then anchored to the temporal fascia and pulled in a cranial direction. The tension and correction on the tissue will indicate how tight to pull the threads. The barbs are engaged with gentle digital pressure over the entire thread. At the exit points, deeply buried suture knots are tied and kept well below the subcutaneous level to avoid suture palpability.
- 9. Thread no. 3 is placed next. This thread corrects descent of the corner of the mouth and improves the lower half of the nasolabial fold and definition of the inframalar area.
- 10. Thread no. 4 corrects descent of the labiomandibular area and improves the labiomandibular fold. For the submalar area and corners of the mouth, the same principles are followed and the sutures are placed deep into the SMAS level in the lower third of the face. Sutures are kept lateral to the nasolabial folds.
- 11. The remaining sutures (nos. 3 and 4) are now secured and tied as described previously.
- 12. Steri-Strips are then applied to the face with cranial-directed traction.
- 13. The patient's face and neck are gently dressed with elastic foam dressing for 48 hours to avoid any initial tension in the wrong direction along the barbed section of the sutures.

#### POSTPROCEDURE PATIENT CARE

Patients are advised to avoid excessive facial mimicking/movement and laughter for 96 hours. Patients are seen in the office after 48 hours for dressing removal. Facial cleansing should be performed in a cranial direction to avoid disengagement of the barbed segment of the sutures within the first week. Acetaminophen and other standard pain medications are recommended for pain, as well as the use of an ice compress on the evening after surgery.

Patients are not ready to return to work or engage in social activities until at least 7 to 10 days after the procedure.

Proper early postoperative care is important. The face must be protected from pressure to avoid disengagement of the cogs from the lifted tissues. Patients are instructed to sleep on their backs. Talking and chewing are to be minimal and limited as much as possible. This may restrict the patient's function at work or socially. Facial and scalp cleansing and washing have to be performed in a cranial direction. All of these precautions should be observed for 2 weeks after the procedure, at which time the connective tissue around the cogs may be strong enough for the patient to engage in more liberal activity.

#### **KEY POINTS**

All threads are placed in the deep subcutaneous plane *above* the zygomatic arch and then pass into the superficial SMAS plane *below* the zygomatic arch. It is here that the barbed portion of the suture interacts with the SMAS so that it is firmly anchored and supports the underlying tissues in a deeper context, similar to a standard facelift technique. This support of the underlying facial musculature and SMAS level creates the initial improvement as well as the long-lasting results desired.

#### **COMMON ERRORS**

- Sutures placed too deeply
- Sutures placed too superficially
- Sutures not anchored securely
- Sutures pulled too tight or not tight enough

#### **COMPLICATIONS**

- Nerve injury (extremely rare)
- Facial asymmetry
- Ecchymoses
- · Skin puckering or dimpling, especially at the suture ends

If any excessive pull or contour deformity is seen after the procedure, the barbs can be released up to 2 weeks after the procedure. This is performed with moderate digital pressure downward over the area that appears to have a "divot" or overtied effect. The bunching effect of skin over the zygoma and postauricular areas and transient tightness and overcorrected look with skin tension improve over the next 1 to 2 weeks, resulting in a very natural appearance.

Furthermore, although it is uncommon, some patients develop significant dimpling at the exit points of the sutures, an uneven contour of facial curvatures with grooving along the cheeks, and waviness and skin folding along the hairline and around the ears. Bruising is rare and resolves within 10 to 14 days. Suture rejection is also rare

#### **DISCUSSION**

The barbed suture technique provides initial marked improvement in the triangle of youth and an extremely high level of patient satisfaction. In our practice we also apply autologous fat injections to the midface as an adjunct procedure to improve midface volume loss. We have noted an initial contraction of the skin in approximately 1 week to 10 days, followed by marked long-term improvement in the patient's overall facial contour. It has been observed that the sutures retain their effect through the formation of a capsule (scarring) around the barbed segments and gradually retract the tissues even more over time. Because the Contour Threads are placed through the SMAS level to ensure final anchoring, it is anticipated that long-term results will be significant, based on the fact that the basic fundamental principles are the same for open facelifting in general.

The "closed form" of the mid-facelift procedure described here can provide approximately 60% to 70% of the results of a standard open facelift procedure. The patient will lose some of the initial lifting results because the immediately apparent postoperative effect relaxes by approximately 30% in the first 6 to 12 weeks (overcorrecting is common because loosening can be performed up to 2 weeks after surgery). The thread lift is certainly not a replacement for the more enduring and proven facelift procedure, nor is it a lunchtime procedure. It is still a surgical procedure that requires local anesthesia and in some select cases intravenous sedation. The degree of facial edema, ecchymosis, discomfort, and tightness can be significant.

If patients have realistic expectations as to the degree of facial rejuvenation attainable with this procedure and understand the need to allow appropriate time for postoperative recovery, then this procedure can yield very good results (Figs. 62-6 and 62-7).

Figure 62-6 Preoperative (A) and postoperative (B) images of neck lift.

**Figure 62-7** Preoperative (**A**), 2-month postoperative (**B**), and 14-month postoperative (**C**) images of combined midface and neck lift.

Barbed suspension sutures for midface rejuvenation are safe and reliable. The technique is relatively easy to perform after a moderate learning curve has been traversed. Nerve injury or facial asymmetry is rare. Like most new procedures, the surgical techniques and technology of barbed sutures have evolved and will likely continue to improve. The final chapter on the barbed suture suspension technique has not yet been written. Despite some controversy, this

procedure will certainly find a place in the cosmetic physician's armamentarium and gain popularity in years to come.

# RADIOFREQUENCY-ASSISTED UPPER BLEPHAROPLASTY FOR THE CORRECTION OF DERMATOCHALASIS

Richard Castillo

Lid droop secondary to redundant skin (*dermatochalasis*) affects nearly all individuals at some point. It is more common on the upper eyelids, but also occurs to a lesser extent on the lower lids. It is typically a bilateral condition, most often manifesting in patients older than 50 years of age. Occasionally, it is observed in younger adults.

Examination of the eyelids reveals redundant, lax skin. An excess fold of skin in the upper lid is characteristic, and the normal upper lid crease may be hidden by the excess tissue. Patients will frequently use the frontalis muscle to augment eyelid opening. This reduces the degree of lid droop, but often results in exaggerated wrinkling or furrowing of the forehead and may lead to muscle tension headaches. Dermatochalasis can present both as a cosmetic problem as well as a functional one by interfering with the superior visual field. In this case, surgical correction is considered *reconstructive* rather than cosmetic.

The introduction of the 4-MHz Dual-Frequency Surgitron (Ellman International, Inc., Oceanside, NY) has made the successful office-based management of dermatochalasis commonplace. The use of the device's unique radiofrequency profile coupled with the proprietary electrode handpieces allow for excellent management of the delicate and highly vascular skin of the eyelid. With proper patient selection, office-based blepharoplasty for the treatment of dermatochalasis is an effective and convenient option (see Chapter 30, Radiofrequency Surgery [Modern Electrosurgery]).

#### **ANATOMY**

Successful surgery on the eyelids requires a detailed knowledge of the normal anatomic structures and their functional relationships. Good surgical outcomes depend on correcting anomalies while maintaining or reestablishing normal anatomic relationships. The anatomy relevant to the successful correction of dermatochalasis is reviewed here. The bibliography at the end of the chapter contains a few excellent text references practitioners may use to supplement the following review.

In the primary position of gaze (i.e., eyes staring straight ahead), the *palpebral fissure* measures anywhere from 9 to 12 mm vertically. The horizontal dimension is generally 28 to 30 mm. The *upper eyelid margin* lies 1.5 to 2 mm below the superior corneal limbus in the adult. The upper eyelid's marginal contour reaches its highest point slightly nasal to the mid-pupillary line. The lower eyelid margin is normally positioned directly at the inferior corneal limbus.

The upper eyelid crease (Fig. 63-1) typically lies 8 to 12 mm above the eyelid margin. It is generally lower in males and higher in females. In non-Asian eyes, the crease needs to be reformed as part of the blepharoplasty procedure to reestablish normal cosmetic appearance. In a large percentage of Asian eyes, the crease may be

lower in position than the aforementioned figures or absent altogether. This factor must be taken into account and discussed with the patient before the procedure so that one does not inadvertently "westernize" an Asian eye against the patient's desires.

The skin of the eyelid is the thinnest skin in the body. The epidermis itself may be only three to four cell layers thick. The combined epidermis and dermis of the eyelid may be only 1 mm thick. The underlying dermis is also scant and poorly defined. It lacks the interdigitations (rete ridges and rete pegs) with the overlying epidermis that are found in thicker skin. Thus, the epidermis is only loosely adherent to the dermis. We exploit this unique characteristic during blepharoplasty by delivering local anesthetic into this space. The skin of the eyelid also lacks the subcutaneous fat present in skin elsewhere. The skin of the eyelid thus lends itself to healing nicely from properly formed incisions. One tends not to see the depressions found in scars in other areas of the body when the collagen fibers and adipose tissue in the dermis are disrupted.

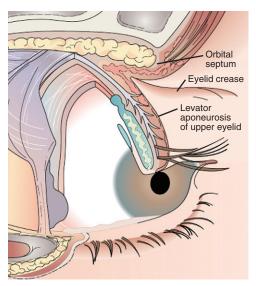

Below the skin of the eyelid lies the *orbicularis muscle complex* (Fig. 63-2). This is a sheet of striated muscle innervated by branches of the facial nerve that acts to close the eyelid. The muscle is subdivided into an *orbital portion*, which overlies the orbital rim, and a *palpebral portion* overlying the eyelid itself. The palpebral orbicularis is further divided into a superior preseptal portion overlying the orbital septum and a pretarsal portion overlying the tarsus of the lid. The pretarsal portion ends medially and laterally in fibers that form components of the canthal tendons that hold the lid margins against the globe. The medial portion is well developed and forms a structure known as *Horner's muscle*. Care must be taken when excising redundant skin from these areas not to damage these structures or resultant lid malpositions may develop. The orbicularis functions not only in eyelid closure but in the proper functioning of the lacrimal system.

Posterior to the orbicularis is an avascular fascial plane composed of loose areolar tissue. Anatomically it separates the orbicularis from the underlying orbital septum—levator aponeurosis complex. This is an important surgical reference plane: it marks the posterior limit of dissection during blepharoplasty for the correction of dermatochalasis.

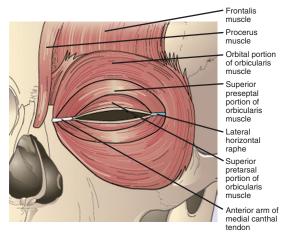

Note the position of the *supraorbital nerve* in Figure 63-3 as it emerges from the *supraorbital foramen*. Care should be taken to avoid this area during administration of anesthesia as well as while making incisions to avoid trauma to this nerve.

#### **INDICATIONS**

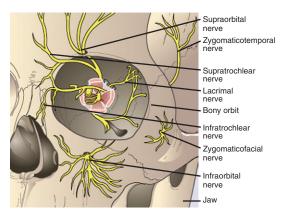

- Dermatochalasis of the upper eyelids without significant prolapse of orbital fat
- Pseudoptosis of the upper eyelids due to redundant skin folds

**Figure 63-1** Schematic showing the components of the eyelid and the invagination that forms the visible lid crease. (Copyright © 2004, Mosby, Inc. All rights reserved.)

**Figure 63-2** Schematic showing the multiple components of the orbicularis muscle. (Copyright © 2004, Mosby, Inc. All rights reserved.)

**Figure 63-3** Sensory nerves of the periorbital area. Note the position of the supraorbital nerve. (Copyright © 2004, Mosby, Inc. All rights reserved.)

Good surgical outcomes depend as much on accurate diagnosis and proper patient selection as on good surgical technique. In the case of blepharoplasty, mistaking a case of "true" ptosis for pseudoptosis, or lid droop attributed solely to dermatochalasis, will inevitably yield a poor surgical result. The correction of true ptosis involves more than removal of redundant skin. It almost always requires dissection posterior to the orbital septum and into the orbit, manipulation of the levator aponeurosis and the levator palpebrae superioris themselves, and dissection of the preseptal fat pads that are contiguous with the orbital adipose tissue. Depending on the etiology of the ptosis, treatment may require fascial slings or tarsectomy. A thorough preoperative evaluation is therefore mandatory to establish a proper diagnosis and determine whether one is dealing strictly with dermatochalasis.

#### **Evaluation of Lid Droop**

- 1. A problem-focused *history* is essential:
  - Rule out systemic conditions possibly associated with ptosis such as myasthenia gravis.
  - History of past ocular disorders (including the lids and surrounding skin)?
  - History of prior ocular surgery?
  - History of wearing contact lenses (giant papillary conjunctivitis secondary to contact lens wear can present as a droopy lid)?
  - Is lid droop congenital or acquired?
  - Gradual or sudden onset?
  - Are there symptoms of visual obstruction, ocular irritation, or dry eyes?
  - Are there complaints of diplopia (suggestive of myopathy, neuropathy, or a mass lesion effect)?
- The physical examination should be aimed at determining the etiology of the lid ptosis, as well as detecting conditions that increase the likelihood of surgical complications.
  - Note the position of the eyebrows. The brows should be at or above the level of the superior orbital rim; otherwise the patient has brow ptosis, which must be dealt with separately.
  - Note the amount of dermatochalasis.
  - Note the presence of and measure the height of the eyelid crease.
     An absent crease is a sign of levator dehiscence and cannot be corrected simply by addressing the dermatochalasis component (if present).

The normal eyelid crease is found anywhere from 8 to 12 mm above the central eyelid margin (in the primary position of gaze).

- Note the position of the upper and lower lid margins in both up gaze and down gaze. The margins should be flush against the globe with lashes directed out. There should be no inversion (entropion) or eversion (ectropion) of the eyelid margins noted.
- Measure levator function. The levator palpebrae superioris is the primary elevator of the eyelid. Measuring levator function is an important component in determining the etiology of the ptosis and can be done as follows: use a millimeter ruler to measure the upper eyelid margin excursion from far down gaze to far up gaze, while blocking frontalis function (manually fix the brow with your hand). Normal for an adult is between 12 to 16 mm of travel. Less than this usually signifies a problem other than dermatochalasis.
- Note any preexisting eyelid scars.
- Are there any palpable masses?
- Are the eyes proptotic?
- Perform a thorough cranial nerve examination.
- Document any degree of preexisting strabismus or diplopia.
- Obtain photographs to document findings. Photographs are taken with the eyes in primary position of gaze (Fig. 63-4), as

**Figure 63-4** Frontal photograph showing redundant skin of the upper lids typical of dermatochalasis (redundant skin). Note the lid margins themselves are in normal position, and pupils free of obstruction. This particular patient would not be expected to show a significant degree of superior visual field restriction.

well as a lateral view (Fig. 63-5). These are essential for reimbursement purposes.

- Perform a screening visual field examination (i.e., tangent screen or automated field) bilaterally with the lids in normal position and then again with the lids held or taped up. To qualify for third-party reimbursement, field testing must show a superior defect within 15 degrees of central vision that improves when the lids are held or taped up. In most cases, an inexpensive tangent screen (Wilson Ophthalmic, Mustang, Okla) testing device can be set up in a small room in the office and the field testing performed by an assistant in less than 5 minutes. One need not perform a full 360-degree field test on each eye. All that is required is one superior isopter mapped out for each eye with the lids in normal position, and then with the lids taped up.
- Note the condition of the external eye.
- Perform ophthalmoscopy.
- Visual acuities (bilateral) are recorded before performing any procedure on or around the eyes.

Once all other potential causes of ptosis have been excluded, a diagnosis of dermatochalasis without other mitigating factors can be established as the cause of the lid droop. Clinically, one should pay close attention to the position of the eyelid margin. Sometimes redundant skin folds must be gently lifted up and out of the way to observe the actual eyelid margin. Normally, the lid margin is 1 to 2 mm below the superior limbus. If the lid margin is at or below the superior pupillary border (or within the pupillary zone) with the patient in the primary position of gaze (i.e., staring straight ahead), reconsider the decision to proceed with surgery. In such a case there is likely a secondary cause of the ptosis exclusive of any degree of dermatochalasis.

**Figure 63-5** Lateral photograph showing skin overhanging the lid margin to rest on the eyelashes.

#### **CONTRAINDICATIONS**

Dermatochalasis with associated fat prolapse: Correction requires more extensive resection of prolapsed orbital fat posterior to the orbital septum.

Any type of ptosis not due solely to dermatochalasis (redundant skin)

- May require more complicated reconstruction such as advancement of levator aponeurosis, repair of aponeurotic dehiscence, or plication of the aponeurosis tendon.
- May further require frontalis suspension techniques, frontalis sling with tarsectomy, supramaximal levator resection, or other steps that require incising the orbital septum and therefore would not be deemed appropriate to attempt in an office setting.

History of previous eyelid surgery: Previous surgical trauma and distorted anatomy may prevent tissues from responding in the expected manner and therefore make outcomes difficult to predict.

History of thyroid orbitopathy (Graves' disease): Potential for exacerbating lagophthalmos, dry eye syndrome, and exposure keratitis. History of dry eye syndrome: Potential for exacerbating preexisting

condition.

History of corneal disease: Potential for exacerbating preexisting condition.

History of keloid scar formation: May make it difficult to predict outcomes based on poor healing response.

Diabetes: May make it difficult to predict outcomes based on poor healing response. Patients may be more susceptible to postoperative infection.

Hypertension: A heightened risk of intraoperative/postoperative hemorrhage.

Anticoagulants: A heightened risk of intraoperative/postoperative hemorrhage.

Pacemakers: Contraindication for certain radiofrequency devices. History of myasthenia gravis

- Difficult to predict final lid height/position.
- May inadvertently overcorrect, causing severe lagophthalmos.
   Any patient who cannot be properly positioned or would otherwise not be an acceptable risk for office-based surgery.

#### **EQUIPMENT AND SUPPLIES**

- Povidone-iodine (Betadine) 10% skin cleanser
- Proparacaine topical ophthalmic anesthetic
- Corneal shields (Ellman International, Inc.)
- Skin marking pen (fine point)
- Millimeter ruler (disposable)
- Two suture-tying forceps without teeth
- Sterile plastic drapes
- Large cotton-tipped applicators
- Sterile 4 × 4 gauze pads
- Lidocaine 2% with epinephrine 1:100,000
- Sterile saline solution
- 0.12-mm toothed forceps
- Westcott scissors (sharp tips)
- Ellman Surgitron Unit (Ellman International, Inc.)
- Empire Micro Needle Electrode for incising the skin (Ellman International, Inc.)
- Coagulation forceps (Ellman International, Inc.)
- 6-0 silk suture
- Needle driver
- Antibiotic ointment

#### **PRECAUTIONS**

Anticoagulants such as aspirin and warfarin should be discontinued (if possible) at least 7 days before the planned procedure to minimize intraoperative bleeding and postoperative bruising. Vitamin E and fish oil can also increase bleeding tendencies in these lax tissues.

- If signs of blepharitis (lid margin infection) are present (i.e., flaking, crusting, debris between the lashes, erythema of lid margins), surgery should be postponed until lids are treated and clear of infection.
- A corneal shield should always be used while making incisions and carrying out dissection with sharp instruments.
- An etiology of "true" ptosis must be ruled out. This would include congenital, myopathic, neurologic, aponeurotic, and posttraumatic causes of lid droop. Prior evaluation by an ophthalmologist or optometrist is important.

# PROCEDURE: UPPER EYELID BLEPHAROPLASTY FOR DERMATOCHALASIS (WITHOUT FAT EXCISION)

- After a diagnosis of pseudoptosis secondary to dermatochalasis, an informed consent form is reviewed with the patient and signed. The patient is given the opportunity to ask questions. Realistic expectations for the surgery are discussed. Patients are informed that the goal of the procedure is to remove the redundant skin obstructing vision along the superior visual field.
- The patient is then escorted into the operative suite and placed in supine position. Monitoring devices (electrocardiography, pulse oximetry) and oxygen may be used at the physician's discretion.
- 3. One drop of a topical ophthalmic anesthetic (e.g., proparacaine) is instilled in each eye.
- 4. Mark the lower incision line.

**NOTE:** Incision lines are marked before administration of subcutaneous anesthetic because administration of an anesthetic bolus will distort normal anatomy and make accurate measurements impossible.

- The lower incision line is marked with a fine-tipped skin marker and placed within the eyelid crease (if present). Otherwise, a new crease position is planned 9 to 12 mm above the central eyelid margin (slightly higher in women and slightly lower in men).
- The line is extended and tapered laterally to the lateral canthus (orbital rim) ending approximately 6 mm above the lid margin. It is often helpful to place the lateral incision line in a preexisting rhytid or "crow's feet" wrinkle line.
- Extend the line medially to the area approximately 5 mm directly above the punctum. Do not extend this line any further medially to avoid trauma to the lacrimal apparatus. The natural contour of the eyelid crease is followed (Fig. 63-6).
- 5. Mark the upper incision line.
  - With the patient's eyes gently closed (and before administration of subcutaneous anesthetic), determine the upper inci-

**Figure 63-6** Marking the incision lines. The incision is carried and tapered laterally to the orbital rim, and no further medially than the superior punctum.

Figure 63-7 The redundant skin is bunched up using smooth forceps to determine the extent of tissue to be excised.

sion line by grasping the excess skin gently directly above the center of the lid margin with a pair of smooth forceps (Fig. 63-7). Use the forceps to grasp (Fig. 63-8) and bunch up the excess skin until the closed eyelids just begin to open (<1 mm). Mark this point with the skin marker. Repeat this process for an additional three or four points medially and three or four points laterally until the outline of the upper incision line is apparent. Again, the normal contour of the lid should be followed (Fig. 63-9).

- The "dots" are now connected, creating a smooth continuous line from the medial to the lateral canthus (Fig. 63-10).
- Care should be taken to ensure that the angle formed by the intersection of the upper and lower incision lines at the lateral and medial canthi does not exceed 60 degrees, or webbing may result if the approach is too steep when the skin margins are sutured together.
- 6. Recheck the amount of skin to be excised by gently "pinching" the upper and lower incision lines together to confirm that the closed eyelids *do not* open more than 1 mm (Fig. 63-11). If this is the case, the patient may be left with an iatrogenic lagophthalmos that could require subsequent repair.
- 7. Administer local anesthetic.
  - Inject 1.0 to 1.5 mL of local anesthetic (lidocaine 1% or 2% with epinephrine) subcutaneously beneath the marked area.
     Care is taken to direct the tip of the needle away from the globe during injection to avoid trauma to the globe itself (Fig. 63-12).
  - Use a 4 × 4 gauze to massage the area to dissipate the bolus of anesthetic.
  - Allow 5 to 10 minutes for the anesthesia to take effect and for the epinephrine to provide some degree of vasoconstriction and hemostasis.
- 8. Cleanse the skin with Betadine 10% or similar surgical preparation formula. This step can be performed while the anesthesia is taking effect. At a minimum, the forehead, periorbital region, eyelids, nose, and upper cheek should be cleansed bilaterally.
- Isolate the surgical field with sterile drapes. Disposable plastic sheets with adhesive along one edge work well. A Nevyas drape retractor (Wilson Ophthalmic Corp.) can be used to keep the drape off the patient's nose and mouth.

**Figure 63-8** Measuring the amount of skin to be excised using the "pinch" method.

Figure 63-10 Marking the superior incision line.

**Figure 63-11** Rechecking the amount of skin to be excised using the "pinch" method. Note the eyelid margins should pull apart no more than I mm.

Figure 63-12 Infiltrative subcutaneous anesthesia using lidocaine 1% with epinephrine 1:100,000. Drapes omitted for visibility.

**Figure 63-13** The Ellman Dual-Frequency Surgitron II Unit. (Courtesy of Ellman International, Inc., Oceanside, NY.)

- Check for adequate anesthesia by pinching along the incision lines with toothed forceps. Administer supplementary anesthetic where needed.
- 11. Place a corneal shield before incising skin.
  - A corneal shield (Ellman International, Inc.) is placed directly over the cornea and sclera of the eye being worked on to minimize the risk of trauma while the skin incision/ dissection is being performed.
  - The shield can be lubricated on the inside with a drop of topical anesthetic and inserted (and removed) with a smooth forceps.
- 12. The Ellman Surgitron (Fig. 63-13) radiosurgical handpiece with Empire needle electrode tip installed is used to make the skin incisions (Fig. 63-14). The unit is set to the cut/coag blended waveform. Care is taken to keep the power setting to the minimum required to create the skin incision. It is helpful to lightly moisten the skin with a wet 4 × 4 gauze because this facilitates the cutting action of the radiosurgical electrode. Gentle tension along the incision line also facilitates creating the incision. Remember that the total thickness of the epidermis and dermis combined is about 1 mm. The depth of the incision is no greater than that required to visualize the separation of the skin margins as the Empire needle moves along the surface of the incision line. Always cut along the inside of the inked incision line.
- 13. Dissect and excise an en bloc skin-muscle flap.
  - Grasp the lateral corner of the skin flap with toothed forceps and tent up the skin in this area. Using the Empire needle electrode and light horizontal strokes, carefully dissect the skin/orbicularis flap free from the underlying orbital septum along the plane of the suborbicularis fascia (Fig. 63-15). Alternatively, one may remove the skin, leaving the orbicularis intact. Carefully cauterize any bleeders encountered with light cautery using either bipolar coagulation forceps (Fig. 63-16) or the lateral edge of the Empire needle electrode itself.

**Figure 63-14** The skin incision is created using the Ellman Empire Micro Needle Electrode set to the blended cut/coag waveform.

Figure 63-15 The myocutaneous flap is dissected free with the Ellman Empire Micro Needle Electrode.

• Once the myocutaneous flap is dissected free of the underlying tissue bed and significant bleeders controlled with cautery, a 4 × 4 gauze soaked in chilled sterile saline may be placed over the exposed bed to constrict remaining bleeders and achieve hemostasis. This can be done while the skin flap is being excised from the other eye.

#### 14. Close the incision.

- With the skin flap excised and proper hemostasis achieved, all that remains is to close the incision. The author's preference is 6-0 silk suture placed in simple interrupted fashion (Fig. 63-17). Alternatively, 6-0 Prolene running sutures may be used.
- The position of the eyelid crease is fixed or reformed by taking a small bite of the underlying fascia as the suture is passed from wound margin to wound margin before it is tied off. Recall that the eyelid crease is usually lower or completely absent in Asian eyes. Both the patient and physician should have a clear understanding of how the eyelid crease will be managed before performing the procedure.
- Antibiotic ophthalmic ointment is applied to the incision lines, monitoring equipment is removed, the face is gently cleansed, and the patient is escorted to the recovery area.

#### SAMPLE OPERATIVE REPORT

See the sample operative report online at www.expertconsult.com.

**Figure 63-16** Light bipolar cautery being applied to small bleeders. Note the relatively blood-free field that is characteristic of radiofrequency dissection.

**Figure 63-17** Placement of simple interrupted sutures using 6-0 silk. The lid crease is reformed by taking small bites of the underlying fascia as the skin edges are reapproximated.

#### **COMPLICATIONS**

Overcorrection (lagophthalmos)

- Usually due to overly aggressive "pinch" estimation while bunching up the excess skin with forceps to establish incision lines.
- A small degree of overcorrection (<2 mm) will usually correct itself with prescribed "force blink exercises" (e.g., blink as hard as you can 10 times then relax. Repeat six to eight times per day for 1 week).
- Overcorrection noticed immediately after surgery may be due to the fact that the orbicularis muscle is still paralyzed from the anesthesia and not functioning fully. This situation is transient and will typically correct itself within a few hours to days.
- If there is any degree of lagophthalmos present, the patient should be given artificial tears to use six to eight times per day to keep the ocular surface (primarily the corneal surface) moist. Antibiotic ointment can be used to protect the ocular surface at night.
- Persistent severe lagophthalmos may require a corrective procedure.

#### Undercorrection

- Usually due to poor technique or too conservative an estimation of how much skin to remove.
- Postoperative edema can give the false appearance of undercorrection.

Cold packs should be started as soon as possible after the procedure and continued for at least 48 hours.

In select cases where edema persists, a short course of oral steroids may be helpful.

Dry eye syndrome/tear film dysfunction

- Typically affects older women.
- Lagophthalmos (as mentioned previously) may cause exposure keratitis.
- Transient decreased blink frequency after surgery can cause dry eye symptoms.
- Any degree of dry eye complaint should be treated first with artificial tear supplementation.
- Persistent dry eye complaints or frank lagophthalmos should be referred for evaluation.

#### Contour deformity

Abnormal/asymmetric lid crease height

#### Hemorrhage

- Some degree of lid ecchymosis is to be expected.
  - Subconjunctival hemorrhage may occur and will resolve spontaneously in 7 to 10 days.
  - Retrobulbar hemorrhage is rare but potentially organ threatening. Features of retrobulbar hemorrhage include massive subconjunctival hemorrhage often accompanied by proptosis of

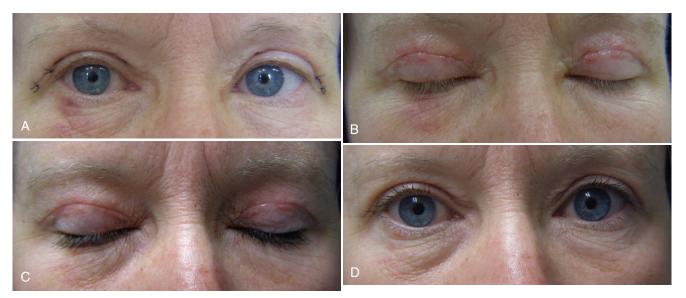

Figure 63-18 A, One week after surgery, before suture removal. Mild edema of the lids is evident. This resolves quickly once sutures are removed. B, One week after surgery with sutures removed. C, Appearance of incisions 2 weeks after surgery. D, Front view 2 weeks after surgery.

the globe. Ocular motility may be affected. There may be a ring of erythema/ecchymosis along both upper and lower eyelids. Pain and decreased vision often accompany this complication. Intraocular pressure is elevated. Check the optic nerve head with an ophthalmoscope. If the optic nerve head is swollen, the patient needs to be referred immediately for an emergent lateral canthotomy. Regardless of nerve status, if retrobulbar hemorrhage is suspected, urgent referral is advised.

Infection: Rare; however, the clinician should diligently examine the incisions and the surrounding skin for signs of infection/cellulitis at all follow-up visits and instruct the patient on how to monitor for signs of infection/cellulitis.

#### **POSTOPERATIVE MANAGEMENT**

- Antibiotic ointment is applied sparingly to the incision lines three times per day for 1 week or until the next follow-up visit.
- Cold packs are applied directly to the lids (alternate 15 minutes on with 15 minutes off every hour while awake) for the first 48 hours. If edema persists, this may be extended.
- Area is to be kept clean and dry by gently cleansing with mild soapy solution (e.g., baby shampoo), which is rinsed with clean water and patted dry (do not rub!). Antibiotic ointment is then reapplied during the first week.
- Patient may use his or her usual choice of over-the-counter pain medication (e.g., Tylenol, Motrin) for discomfort if needed. Prescription-strength painkillers are generally not indicated.
- The patient is to return to clinic in 5 to 7 days for suture removal (Fig. 63-18).
- The patient should be advised to try to avoid direct sunlight for prolonged periods. If the patient is going to be outdoors, he or she should wear sunglasses with ultraviolet protection or a hat with a wide brim.
- After discontinuation of the antibiotic ointment at 1 week, the patient should continue to use a good skin moisturizer (preferably with a sunblock) along the incision lines for up to 8 weeks.
- The patient should be advised that the incisions will continue to heal for a period of 3 to 6 months and that the incision lines will gradually fade over the next 6 months to 1 year.

#### **CPT/BILLING CODES**

15823 Blepharoplasty, upper lid excessive skin weighting down

- For bilateral procedures add -50 modifier.
- Major surgical follow-up global period of 90 days.
- 150% total payment (adjustment) for bilateral procedures applies.

#### **ICD-9-CM DIAGNOSTIC CODES**

374.33 Mechanical ptosis

374.87 Dermatochalasis

# GINGIVAL MELANIN HYPERPIGMENTATION

Ali Gürkan • Fatih Arikan

Hyperpigmentation of the gingiva is caused by excessive deposition of melanin. It is more frequently observed in Asian, African, and Mediterranean populations, and has also been called racial or physiologic pigmentation. Pigmentation may vary not only among subjects of the same ethnic background but within different regions of the mouth. This kind of pigmentation presents as a welldemarcated, bilateral, dark brown, asymptomatic coloration in the keratinized gingiva, mostly in the anterior region. It is due to melanocyte overactivity; both dark- and light-skinned subjects have similar numbers of melanocytes in the gingiva. Because toxic agents in tobacco smoke induce melanocytes to produce melanin, smoking can cause hyperpigmentation in subjects with light skin and may aggravate pigmentation in dark-skinned individuals ("smoker's melanosis"). The severity and extent of melanosis are usually correlated with the duration and quantity of smoking, and the condition improves after the cessation of smoking.

Gingival melanin hyperpigmentation is an aesthetic problem rather than a medical problem. The appearance of the gingiva while smiling is essential to overall personal aesthetics. Because brownblack melanotic lesions mostly involve the anterior vestibular gingiva, they cause an unaesthetic smile. Therefore, depigmentation procedures have attracted much interest, and numerous techniques have been introduced to reverse this change. A novel gingival melanin depigmentation method using radiofrequency (RF) surgery offers advantages over other depigmentation methods, including speed, reliability, lack of postoperative pain, virtually no bleeding, and no discomfort from local anesthetic injection (Table 64-1).

#### **DIFFERENTIAL DIAGNOSIS**

The patient presenting with pigmented gingiva should be thoroughly evaluated regarding dental and medical history, and have an extraoral and intraoral examination as well as laboratory tests when indicated. Addison's disease (adrenal insufficiency) can also cause gingival hyperpigmentation.

Assess the following:

- Smoking habit (duration and number per day)
- Duration of pigmentation
- Skin pigmentation
- Perioral pigmented lesions (lips, face)
- Systemic diseases (e.g., Addison's)
- Systemic symptoms of malignancy (fatigue, malaise, weight loss)
- Medications
- Lymph nodes
- Characteristics of the pigmented lesions (size, number, distribution, shape, color, surface, and borders)

A biopsy should be performed if a lesion cannot be explained by other factors.

#### INDICATION

The removal of gingival melanosis.

#### **CONTRAINDICATIONS**

- Cardiac pacemakers, cardiac defibrillator implants, cochlear implants (relative contraindication)
- Uncooperative patient

#### **EQUIPMENT**

- RF device (see Chapter 30, Radiofrequency Surgery [Modern Electrosurgery]).
- Small ball-tip (no. 135; Ellman International, Inc., Oceanside, NY) or, preferably, L-shaped advanced-composition alloy electrode (Ellman no. 136); the L-shaped electrode has a flat end, making it suitable for a "tapping" action.
- 10% lidocaine spray.
- Mouth retractor.

#### **TECHNIQUE (DUAL FREQUENCY)**

- Place the retractor and apply anesthetic spray to the region of interest.
- Adjust the device to the cutting mode (10 to 11) for thick gingiva or to the coag mode (7) for thin gingiva.
- Melanocytes are primarily located in the basal and suprabasal cell layers of the epithelium. Therefore, touch the pigmented areas lightly with the electrode tip. Remove the electrode as soon as the tissue around the electrode turns whitish. A "tapping" type approach covering all the pigmented areas works best (Fig. 64-1).
- Repeat the procedure for all pigmented areas.
- During the following week, slight redness is observed around the margins of the RF-treated lesions.
- Epithelialization is completed in 10 days, and at 2 weeks after the first treatment, a second procedure can be performed to treat any residual pigmentation.

Figures 64-2 through 64-5 illustrate the results of RF surgical treatment of gingival hyperpigmentation in a variety of cases.

#### POSTPROCEDURE CARE

- Gentle brushing
- Antiseptic rinse
- Analgesic drugs the day of surgery (usually not needed)

TABLE 64-1 Comparison of Gingival Depigmentation Methods						
Method	Bleeding	Needle Anesthesia	Post- operative Pain	Periodontal Dressing	Ease of Access to Interdental Papillary Region	Major Disadvantage of Method
Scalpel surgery	+	+	+	+	_	Bleeding
Particle abrasive methods	+	+	+	+	_	Bleeding
Laser	_	+	_	_	+	Expense
Gas cryosurgery	_	_	_	_	-	Safety
Tetrafluoroethane (TFE) cryosurgery (e.g., Envirotech Freezer Spray, Medi-Frig, and Verruca-Freeze)	-	-	-	_	-	Lack of access to interdental papillary region
Radiofrequency surgery	_	_	_	_	+	None

**Figure 64-1** Tapping the electrode on the pigmented gingival tissues. A topical anesthetic has been applied.

**Figure 64-2** Clinical view of a case before and after the procedure.

**Figure 64-3** Total removal of heavily pigmented lesions with two RF sessions over a 4-week period.

**Figure 64-4** Clinical view of a case before and 6 months after RF depigmentation treatment.

#### **COMPLICATIONS**

- If the electrode is held in place longer than necessary or if too high a setting is used, excessive tissue necrosis can occur, increasing postoperative pain and compromising healing.
- We have never observed hypopigmentation of the pigmented gingiva after treatment. The brown gingiva becomes pale pink like the neighboring tissues after the healing period at 2 weeks. We have followed these patients for up to 1 year and observed no recurrence, even when they have not changed their smoking habits. In the event of recurrence, the simple procedure can be easily repeated. All of our patients indicated they were willing to repeat the procedure if needed, scoring their satisfaction with the results as "excellent."

### CHALAZION AND HORDEOLUM

James L. Jackson

Patients with a chalazion or hordeolum, focal inflammatory conditions of the eyelids, are frequently encountered in primary care. Invariably they complain of a "stye." Both conditions may be treated by the prudent nonophthalmologist using a minor surgical procedure in the office setting. However, care must be taken not to injure the eye, the eyelid, or sensitive components, particularly the lacrimal drainage system ("tear ducts") or the eyelid margin.

A *chalazion* (Fig. 65-1) is an acute or chronic granulomatous inflammation of a meibomian gland in the eyelid. A *hordeolum* is an acute abscess of a meibomian, Zeis', or Moll's gland (see Fig. 65-10). An *internal hordeolum* points onto the conjunctival surface of the lid, whereas an *external hordeolum* points onto the external surface of the skin or the margin of the lid.

The meibomian glands are basically sebaceous glands located deep within both eyelids (Fig. 65-2). They constantly produce a lipid material that drains through long ducts and emerges from orifices at the eyelid margin. This lipid material then enters the tear film to help keep the surface of the eye lubricated while also slowing evaporation of the tears.

Meibomian secretions are naturally viscous, but under certain conditions they become thick enough to plug the duct of the gland. Because the gland continues to produce secretions, they must go somewhere (similar to a sebaceous cyst); consequently, the secretions eventually leak between the cells of the gland into the surrounding tissue of the eyelid. Here, the secretions incite a chronic granulomatous inflammatory reaction (*chalazion*). As more secretions are produced, the inflammation worsens and it may smolder chronically, sometimes for a year or longer.

Clinically, the inflammation causes localized swelling, edema, or a nodule within the lid, sometimes associated with erythema and mild tenderness. A chalazion may be located at the lid margin or up to a few millimeters away. At times it may be prominent externally, but more commonly a chalazion will be found on the inner (palpebral conjunctiva) surface of the lid. Associated inflammation may cause a soft or even liquid center, and patients may report spontaneous drainage internally, externally, or through the lid margin, which may lead to clinical improvement or resolution. A chalazion may also wax and wane.

Some people experience multiple chalazia over time or even concurrently. Multiple chalazia are more commonly seen in people with acne rosacea or chronic blepharitis. Chronic blepharitis is characterized by eyelid margin inflammation, thickening, and erythema associated with bacterial colonization and crusting at the base of the eyelashes. Chronic blepharitis usually requires a slit-lamp examination to make the diagnosis (see Chapter 67, Slit-Lamp Examination); even with a slit lamp, the findings are often subtle and not easily detected by the nonophthalmologist.

In contrast to a chalazion, a hordeolum is an acute bacterial abscess of a meibomian, Zeis', or Moll's gland (see Fig. 65-2). Hordeola are classified as internal or external based on the primary anatomic focus of the inflammation (which is usually obvious). Typically characterized by an acute tender mass within the eyelid, associated with erythema and a collection of pus, hordeola are often

accompanied by acute cellulitis of the eyelid. Such cellulitis, in turn, is characterized by erythema, edema, and tenderness of the surrounding skin. ("Eyelid cellulitis" is a different, much more localized entity than the less common "orbital cellulitis," a systemic, visionand life-threatening condition with which the patient is toxic with a high fever.) A hordeolum usually drains spontaneously at 5 to 7 days, often relieving the symptoms. Hordeola are frequently associated with *Staphylococcus* infections and acute blepharitis, and these both usually respond to antibiotics.

To differentiate a chalazion from a hordeolum can be a clinical challenge. Although a hordeolum is usually more tender and tense with obvious fluctuance, a chalazion may have a liquefied center; however, it is usually not a collection of pus. The presence of significant eyelid cellulitis also usually suggests a hordeolum, but a chalazion may be associated with a degree of surrounding erythema and edema (although it is usually to a lesser degree). The natural history of a hordeolum is usually more acute; yet, a chalazion can present acutely. It may also be important to differentiate a chalazion or hordeolum from other eyelid disorders. If the swelling is located nasal to the medial canthus (the corner where the upper and lower eyelids meet), the patient likely has dacryocystitis rather than a chalazion or hordeolum. In this situation, strongly consider prompt referral to an ophthalmologist because dacryocystitis can lead to serious sequelae. Because of the facial anatomy, bacterial dacryocystitis can dissect posteriorly to the cavernous sinus and beyond, with grave consequences.

#### **CHALAZION**

#### **Medical Management**

A chalazion may respond to one or more of the following medical treatments:

- Warm compresses to the eyelid (four times a day if possible).
- Eyelid scrubs of the lid margins at bedtime each night (at base of eyelashes) with commercially available ocular cleansing pads or diluted baby shampoo (diluted to half strength with water, applied with a cotton swab or washcloth).

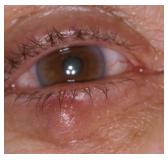

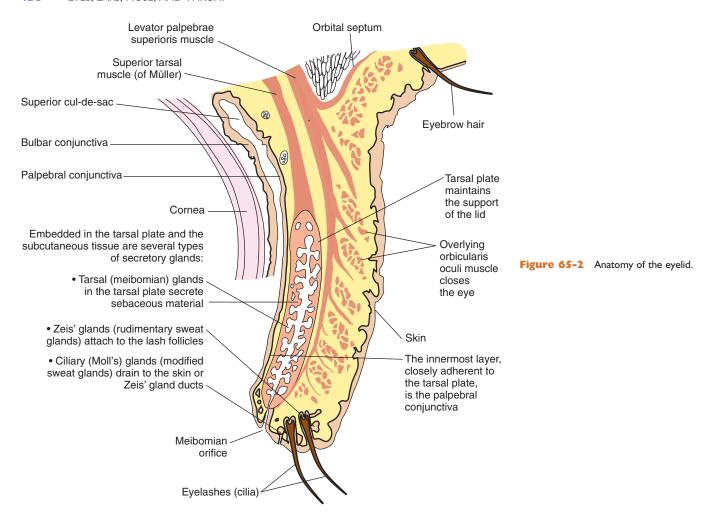

Figure 65-1 Chalazion, lower lid.

- Application of antibiotic ointment (usually erythromycin) to eyelid margin after washing.
- Oral doxycycline.
- Intralesional steroid injection (e.g., triamcinolone acetonide) 40 mg/mL, 0.2 to 0.4 mL, 30-gauge needle through the conjunctival (inner) surface of the eyelid, after the use of topical anesthesia (e.g., tetracaine drops). However, steroid injection carries the risk of skin hypopigmentation, especially in dark-skinned individuals.

#### **Indications for Excision**

- Chalazion unresponsive to medical management
- Substantial size (large enough to palpate)
- Cosmetic deformity
- Visual problems (e.g., astigmatism, blurry vision)
- Patient desires removal

#### **Contraindications to Excision**

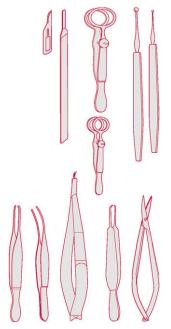

- Chalazion that has recently drained through the skin or with very thin overlying skin (relative contraindication, increases risk of a full-thickness "buttonhole" defect of the eyelid, leading to a visible scar and prolonged healing time).
- Skin crusted or markedly inflamed (excision is usually performed from the inner surface of the eyelid and, again, a "buttonhole" defect may result).
- Anticoagulated patient (relative contraindication).

• Chalazion near the lacrimal punctum. The lacrimal punctum is a tiny opening in the nasal aspect of each eyelid margin. Tears drain through the punctum into the canaliculus, which runs just beneath the skin toward the nose. Damage to the punctum or canaliculus may lead to chronic tearing and the need for a complicated surgical repair. If the chalazion is close enough to the punctum that there is a chance it has been damaged, the patient should be referred to an ophthalmologist for excision.

#### **Equipment**

See Figure 65-3.

- Mask and goggles to follow universal blood and body fluid precautions
- Sterile tray
- Skin marking pen
- Topical ophthalmic anesthetic drops (e.g., tetracaine)
- Alcohol pads
- Local anesthetic for injection (2% lidocaine with epinephrine),
   3-mL syringe, 30-gauge needle
- Povidone–iodine (Betadine) swabs
- Sterile gloves
- Sterile drape, fenestrated
- Chalazion clamps (two or three sizes)
- Scalpel (no. 15 blade)
- Chalazion curettes (two sizes)
- Cotton swabs

**Figure 65-3** Instruments for chalazion excision. *Top row, from left to right:* scalpel (no. 15 or no. 11 blade); chalazion clamps; chalazion curettes. *Bottom row, from left to right:* ocular tissue forceps; needle holder; suturing forceps; Westcott conjunctival scissors.

- Ocular tissue forceps, 0.2 tips
- Westcott conjunctival scissors
- 4 × 4 gauze pads
- Antibiotic-steroid combination ophthalmic ointment (e.g., Maxitrol or TobraDex)
- Eyepatches (two or three) and medical tape
- Suture (6-0 nylon), needle holder, and suture scissors (only in event of full-thickness eyelid defect occurring as a complication)

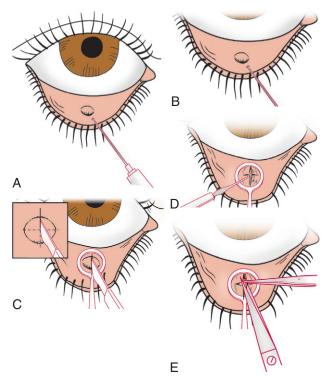

#### **Preprocedure Patient Preparation**

Unless the patient is at high risk of cardiovascular events, he or she should discontinue aspirin or other antiplatelet medications for 1 week and anticoagulants for 4 days before the procedure. The patient should be counseled about the risks for scarring, a possible need for sutures, the risk of recurrence and need for repeat excision, short-term swelling/bruising of eyelid, excessive bleeding, infection, and, rarely, damage to the lacrimal drainage system resulting in chronic tearing. It will be important for the patient to remain motionless during the procedure. The patient may experience some discomfort and tearing with injection of the anesthetic.

#### **Technique**

Universal blood and body fluid precautions should be followed. The clinician can achieve good access to the eye by sitting near the top of the head. The patient should lie supine. Good lighting is essential. Injection of the local anesthetic may make palpation of the chalazion difficult, so it is helpful to use a skin marker before injection.

- 1. Administer several drops of a topical ophthalmic anesthetic. Then inject 2% lidocaine with epinephrine through the skin, infiltrating the area where the chalazion clamp is to be applied (Fig. 65-4A).
- 2. Place a chalazion clamp over the chalazion, with the open side inside the eyelid (Fig. 65-4B). Avoid damaging the eyelid margin. Tighten the clamp to achieve a firm grip on the eyelid, which

**Figure 65-4** Chalazion excision. **A,** Inject anesthetic. **B,** Place chalazion clamp. **C,** Incise with scalpel, making an "X" over the lesion. **D,** Curette interior of chalazion to remove soft, inflamed material. **E,** Remove small amount of inflamed tarsus with Westcott conjunctival scissors and tissue forceps.

will maintain hemostasis during the procedure. Do not overtighten. Evert the eyelid using the clamp as a lever (Fig. 65-5). The chalazion should now be evident and bulging through the opening of the clamp.

- 3. With a no. 15 blade, make two incisions in the form of a cross, taking care not to go through the eyelid skin but only into the substance of the chalazion (Fig. 65-6; Fig. 65-4C). Some soft material may be released, confirming that the incision is in the correct location.
- 4. Use the curettes and cotton swabs to remove as much soft, inflamed material as possible (Fig. 65-7; Fig. 65-4D). Remove as much granulation tissue as you can with forceps (Fig. 65-8).
- 5. Using the Westcott conjunctival scissors and tissue forceps, remove a small amount of the inflamed tarsal plate (the cartilage underneath), if necessary (Fig. 65-4E). Take care not to tent the deeper tissue, which can lead to inadvertent incision of the underlying skin and cause a "buttonhole" defect. Again, avoid damaging the eyelid margin.

**Figure 65-5** After topical anesthetic drops are instilled, a chalazion clamp is used to stabilize and evert lid.

Figure 65-6 Incising the chalazion using a no. 15 blade. Make an "X" over the lesion.

Figure 65-7 Removing contents with a chalazion curette.

Figure 65-8 Removing granulation tissue with forceps (pickups).

Figure 65-9 Postoperative appearance after chalazion removal.

- 6. Remove the chalazion clamp, which will likely lead to significant bleeding because of the excellent vascularity of the eyelid. Apply direct pressure with cotton swabs or gauze pads to achieve hemostasis. This may take 5 to 10 minutes (Fig. 65-9). Once hemostasis has definitely been achieved, apply an antibiotic–steroid eye ointment and place a pressure patch on the eye (see Chapter 66, Corneal Abrasions and Removal of Corneal or Conjunctival Foreign Bodies, Fig. 66-5, for a technique on pressure patching).
- 7. If a full-thickness eyelid defect is present, suture the outer skin while taking care that the suture does not include the conjunctival (inner) surface of the eyelid; this would cause a great deal of irritation and possibly a corneal abrasion. If damage to the lacrimal punctum or canaliculus occurs inadvertently, promptly refer the patient to an ophthalmologist.
- 8. Beware of recurrent or multiple chalazia in older patients, especially with associated ocular inflammation. This could represent sebaceous cell carcinoma, which is very aggressive and not always noted on pathologic examination of an excised chalazion. If a presumed chalazion does not behave as expected after excision, particularly in an elderly patient, sebaceous cell carcinoma should be suspected even if the initial pathology report is negative. In that situation, the patient should be referred to an ophthalmologist.

#### **Postprocedure Patient Education**

The patient may remove the patch the evening after the procedure. Tell the patient that he or she can expect a large amount of clotted blood and mattering of the eyelid. The patient should then begin to apply an antibiotic eye ointment (e.g., erythromycin) in the eye twice a day until judged "back to normal." If the eyelid begins to bleed again, the patient should apply pressure until it stops, and should seek medical attention if the bleeding does not stop. If sutures were placed, they should be removed in 5 days.

#### **HORDEOLUM**

#### **Medical Management**

If less severe and not yet "pointing," the hordeolum may be treated with frequent warm compresses and an oral antibiotic directed against *Staphylococcus*. In fact, most hordeola respond to this management, with spontaneous drainage and resolution occurring in 5 to 7 days. However, if the patient is being treated medically, he or she should be watched closely in case the need for incision and drainage develops.

#### Indications for Incision and Drainage

- Hordeolum that fails medical management (Fig. 65-10)
- Hordeolum causing significant pain
- Hordeolum with significant localized accumulation of pus
- Previous or current eyelid cellulitis associated with hordeolum

Figure 65-10 Hordeolum of upper lid.

#### Contraindications to Incision and Drainage

If the hordeolum is located near the lacrimal punctum (i.e., located nasal to the medial canthus), refer the patient to an ophthalmologist because of the risk of damaging the lacrimal drainage system.

#### **Equipment**

- Mask and goggles to follow universal blood and body fluid precautions
- Topical ophthalmic anesthetic drops (e.g., tetracaine)
- Alcohol pads
- Local anesthetic for injection, 2% lidocaine with epinephrine, 3-mL syringe, 30-gauge needle
- Nonsterile gloves
- Scalpel (no. 11 blade)
- Cotton swabs
- 4 × 4 gauze pads
- Tongue blade or metal elevator

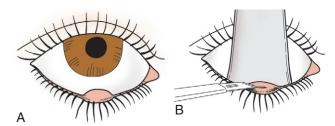

#### **Preprocedure Patient Preparation**

Unless the patient is at high risk of cardiovascular events, he or she should discontinue aspirin or other antiplatelet medications for 1 week and anticoagulants for 4 days before the procedure (although it is usually necessary to perform the procedure without much advanced planning). The patient should be counseled about the risks of scarring, recurrence, and need for repeat incision and drainage, short-term swelling/bruising of eyelid, excessive bleeding, spread of infection, and, rarely, damage to the lacrimal drainage system resulting in chronic tearing. It will be important for the patient to remain motionless during the procedure. The patient may experience some discomfort and tearing with the injection of local anesthetic.

#### **Technique**

Universal blood and body fluid precautions should be followed. The hordeolum will point either internally or externally and should be incised from whichever surface allows the best access to the collection of pus (Fig. 65-11A).

- 1. Administer several drops of topical ophthalmic anesthetic. Then administer 2% lidocaine with epinephrine through the skin, infiltrating the area around the hordeolum. (Remember that anesthesia is more difficult to obtain in the presence of inflammation.) A tongue blade or metal elevator can be inserted behind the lid to protect the eye (Fig. 65-11B). It may be helpful to stabilize the hordeolum and lid with a chalazion clamp (Fig. 65-12).
- 2. Use a no. 11 scalpel blade to make an incision into the hordeolum until pus is obtained, taking great care to avoid a throughand-through eyelid defect or injury to the eyelid margin or eye. If significant cellulitis is present, it may be prudent to send a sample of the pus for culture and sensitivity testing.
- 3. After the pus is expressed (Fig. 65-13), apply direct pressure with gauze pads to achieve hemostasis. This may take 5 to 10 minutes. An eyepatch is not necessary.

**Figure 65-11** Hordeolum excision. **A,** Hordeolum pointing externally. **B,** Incision and drainage of external hordeolum, with a tongue blade or metal elevator protecting the eye.

Figure 65-12 Stabilizing the hordeolum with a chalazion clamp.

4. If a full-thickness eyelid defect is present, do not suture the skin because of the presence of acute bacterial infection. Consider appropriate systemic antibiotic therapy for significant cellulitis of the eyelid. If damage to the lacrimal duct occurs inadvertently, promptly refer the patient to an ophthalmologist.

#### **Postprocedure Patient Management**

If the eyelid begins to bleed again, the patient should apply pressure until it stops and should seek medical attention if he or she is having difficulty controlling the bleeding. The patient will be given an oral antibiotic (with good coverage for *Staphylococcus*), and should be seen the next day. He or she may need to be seen daily for several days after the procedure until it is evident that the cellulitis is resolving and that pus is not reaccumulating. The patient should make an appointment in 2 to 3 weeks to further assess healing. It may take several weeks for the swelling and tissue distortion to return to normal.

# CORNEAL ABRASIONS AND REMOVAL OF CORNEAL OR CONJUNCTIVAL FOREIGN BODIES

Grant C. Fowler

Patients with "something in the eye," a corneal or conjunctival abrasion or foreign body, are common for primary care clinicians. In most cases, the management is uncomplicated and can be completed in the clinician's office; however, knowledge of certain principles should help avoid impaired vision or blindness.

A detailed history is important, especially knowing what the patient was doing when he or she first noticed a problem. For instance, was the patient wearing eye protection? Was he or she around hammered metal? Did he or she come into contact with a high-velocity foreign body?

NOTE: In the past, corneal abrasions were treated with eye patching and mydriatics; however, there is little evidence to support such therapy, and eye patching may even impede healing. Consequently, most clinicians now use ophthalmic nonsteroidal anti-inflammatory drugs (NSAIDs) and an ophthalmic antibiotic for treatment. Some of the evidence supporting this approach is discussed further in the "Technique" section. Also, if a slit lamp is available, a more thorough evaluation of the eye may be performed for a corneal abrasion or foreign body (see Chapter 67, Slit-Lamp Examination). In the absence of a slit lamp, this chapter indicates when a slit-lamp referral is required.

## FLUORESCEIN EXAMINATION OF THE CORNEA AND CONJUNCTIVA

#### **Indications**

- Unilateral foreign body sensation, hypersensitivity to light, excess tearing, or pain—especially on opening or closing the eye
- Red eye
- Eye trauma
- After airbag deployment in automobile accidents
- Unilateral, persistent eye irritation in contact lens wearer
- History of exposure to ultraviolet (UV) light from such sources as a welding torch, sunlight, or a tanning bed (UV light can penetrate the cornea even when the patient's eyes are closed if protective lenses are not worn)
- Mild chemical exposure to eye
- Neonates or infants with persistent crying, unilateral tearing, hypersensitivity to light, or conjunctival inflammation
- Eye discharge in mask-ventilated newborn or heavily sedated or paralyzed adults on a ventilator

NOTE: Hypersensitivity to light, excess tearing, and painful or red eye are also signs and symptoms of glaucoma (see Chapter 68,

Tonometry). If there is no foreign body sensation, the patient should be evaluated for acute glaucoma.

#### **Contraindications**

Patients with the following symptoms should be referred to an ophthalmologist after they have been provided initial urgent care:

- Suspected high-velocity injury to the eye (e.g., patients exposed to metal hammering or heavy machinery). High-speed metallic or nonmetallic fragments can penetrate the globe while only causing minimal symptoms and damage to the cornea. As a result, significant internal damage must be excluded. If penetration of the globe is apparent, fluorescein staining is usually avoided because it may make further evaluation or surgery more difficult.
- A hyphema, lens opacification, scleral tear, abnormal anterior chamber examination, or irregularity of the pupil. These findings suggest that the globe has been penetrated, and an ophthalmologist needs to be involved. Orbital x-ray films may confirm a metal foreign body. A spiral computed tomography scan or ultrasonography may also confirm a metal foreign body; magnetic resonance imaging is contraindicated if there is a possible ferromagnetic object.
- Long-standing (>24 hours) inflammation as evidenced by iritis, photophobia, or ciliary blush. These findings suggest the presence of an intraocular foreign body or a more serious injury and require slit-lamp examination and evaluation by an ophthalmologist.

NOTE: A pressure patch is contraindicated in a penetration injury of the globe or a complex lid laceration. For such injuries, a nonpressure protective eye shield should be applied before referral. Metal shields are manufactured for this purpose, or a nonpressure shield can be fashioned from a paper cup (Fig. 66-1). All patches and shields should be taped in the same direction, from the medial forehead across the eye and toward the ear.

- Exposure to caustic or acidic media. Immediate management includes copious irrigation for at least 15 minutes. (It can begin at home with tap water from a shower or hose.)
- Mild chemical exposure. If the clinician is not knowledgeable about or comfortable with managing the case after contacting a Poison Control Center, the patient should be referred.
- Ruptured globe.
- Uncooperative patient. (Infants may have to be sedated; see Chapter 7, Pediatric Sedation and Analgesia.)

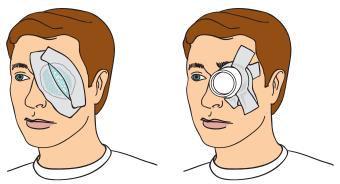

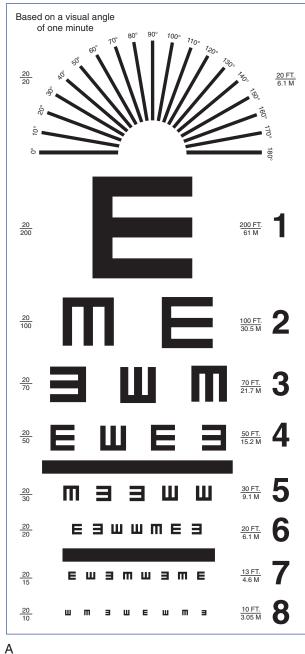

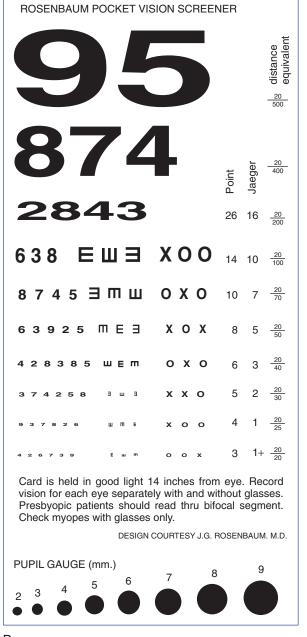

Figure 66-I Nonpressure patch to protect ruptured globe. A metal shield or a paper cup can be used.

#### **Equipment**

- Snellen chart at 6 m (20 ft), or an equivalent visual acuity chart (Fig. 66-2). If a chart is unavailable, ask the patient to read a magazine at arm's length. If the patient cannot do so, measure and record the distance at which the patient can count fingers.
- Topical ophthalmic anesthetic such as 0.5% proparacaine (e.g., Alcaine, Kainair, Ophthaine, Ophthetic, Paracaine, Proparacaine), unless contraindicated (e.g., ruptured globe or allergy to local anesthetics).
- Sterile fluorescein sodium strips. (Because fluorescein is incompatible with preservatives effective against Pseudomonas and Proteus, multidose dropper bottles of fluorescein solution should not be used. Inoculating abraded corneal epithelium with bacteria could cause infection, permanent scarring, or blindness.)

- Bright white light source (a single-point source such as a penlight is preferable).
- Cobalt-blue light source (Wood's lamp is adequate).
- An 8- to 10-power magnification lens (loupes, a magnifying glass, a colposcope, or an ophthalmoscope on the +20 to +40 diopter setting).
- Sterile cotton-tipped applicators.
- Isotonic ophthalmic irrigant (e.g., Dacriose, Ringer's lactate, normal saline).
- Facial tissues (e.g., Kleenex).

#### **Preprocedure Patient Preparation**

The indications for the examination should be explained to the patient as well as any risks or alternatives. The patient needs to know what will occur during the examination, and that he or she may be asked to direct vision to certain locations. Eyedrops and dye will probably be necessary to enhance the examination. Contact lenses should be removed before the eye is stained (fluorescein can stain them permanently). Before instilling fluorescein, the patient should be warned that objects in his or her vision may temporarily appear yellow. Tears may also remain yellow for a short time after the examination and might stain skin or clothing, at least temporarily, so the patient should avoid rubbing his or her eyes or drying tears on something that might stain.

Patients should be instructed to breathe normally and, especially children, may be asked at certain times to remain as still as possible. Children may need assistance with holding still. Patients should know to blink normally unless their eye is being held open by the examiner or they are asked to hold their eye open. They should be aware of the need for the examiner to touch their face and even to pull on their evelids. Before instilling the topical anesthetic, tell the patient that it may cause a burning sensation until the eye becomes numb. Because patients with a corneal abrasion are usually hypersensitive to light, let them know when you are going to need a bright white light for only a short while, and that the room will otherwise be darkened. The remainder of the examination is done with a blue light, which should be more comfortable. Reassurance that this bright light will not cause permanent visual damage is usually appreciated. In fact, patients should be told that the reason for using this bright light (in most cases) is to prevent permanent damage to their vision. After the clinician has located the necessary equipment, the lights in the room can be dimmed during the remainder of the examination.

If an abrasion is diagnosed, emphasize the need for the patient to follow up daily with the clinician until it is completely healed. This will detect early complications such as infection. Instruct the patient to call the office if persistent or recurrent symptoms occur. Patients should also be instructed not to drive if the abrasion impairs their vision or depth perception.

#### **Technique**

1. Check and document visual acuity in both eyes *before* instilling topical anesthetic. Documentation of baseline visual acuity *before* the topical anesthetic is applied is important because initial discomfort due to the anesthetic (e.g., burning, stinging) may later be suspected by the patient as having caused impaired vision. If the patient normally wears corrective lenses (e.g., glasses) for refractive error, check visual acuity with refraction. After the acuity check, the patient will probably be most comfortable in the supine position for the remainder of the examination.

NOTE: If the patient's corrective lenses are not available, a pinhole myopia corrector can be used. These are commercially available, but they are also easy to make. With an 18-gauge needle, punch 8 to 10 holes within a 5-cm (2-inch) circle on an index card. Have the patient select the hole that provides the best vision when viewing the Snellen chart. This effectively corrects the patient's vision.

- 2. Hand the patient a tissue and instill one to two drops of topical anesthetic into his or her affected eye. (This is not mandatory but does facilitate patient cooperation and comfort.)
- 3. Inspect the affected eye, briefly but thoroughly, with a bright white light source, and compare it with the opposite eye. The sclera should be intact. The anterior chamber should be free of pus or blood. The iris should be normal in size and shape. The pupil should be normal in size, shape, and reactivity, and it should be symmetric with the other pupil unless there is a history of asymmetry (anisocoria). If all of these conditions are not met, the patient should be referred to an ophthalmologist.
- 4. Eversion of the upper lid is usually necessary to examine the entire conjunctiva (Fig. 66-3). After grasping the lower lid and applying traction, examine the conjunctiva beneath it as well. Inspect the entire bulbar and palpebral conjunctiva for trauma, foreign body, or other sources of symptoms, such as a hordeolum or an ingrown or inverted eyelash. Examine carefully the groove about 2 mm from the lash margin of the everted lid. Tiny objects frequently lodge here and may not be immediately visible. Use the ophthalmoscope for magnification if necessary. For a foreign body, refer to the "Corneal or Conjunctival Foreign Body Removal" section later in this chapter. Older patients often have ingrown hairs (trichiasis) that can cause a foreign body sensation

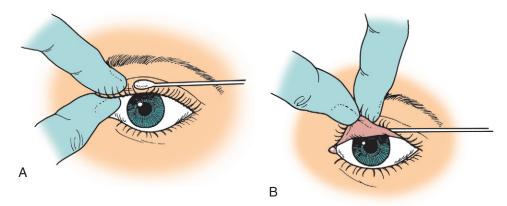

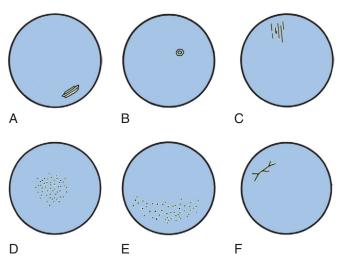

Figure 66-3 A, Grasp the upper eyelashes between the thumb and index finger. With the tip of the other index finger or a cotton-tipped applicator, press down gently on the skin of the upper lid. B, Pull outward on the lashes and rotate the tarsal plate upward until it forms a right angle with the eyeball. A gentle tug upward should flip the plate into eversion, clearly exposing the conjunctival surface of the upper lid.

(see Chapter 39, Epilation of Isolated Hairs [Including Trichiasis]). Trichiasis most frequently involves the lower lid, and if there are only a few hairs, they can be plucked out with fine forceps. The patient with many hairs should be referred for electrolysis of the roots.

- 5. Instill fluorescein dye by moistening a sterile fluorescein strip with one or two drops of sterile saline or topical anesthetic, asking the patient to look up, and gently touching the lower conjunctival sac for 3 to 5 seconds. Use a minimal amount of solution when wetting the strip. This usually helps visualize the defect by staining only the defect as opposed to staining the entire eye. Try not to touch the cornea directly with the strip because this may cause iatrogenic staining. After instilling the fluorescein, have the patient blink a few times to remove excess tears, and blot them with the tissue. This is helpful to distinguish true staining from fluorescein saturation of the tear film.
- Inspect the cornea with magnification under a cobalt-blue light source. If the entire cornea is stained, irrigate the eye again and re-examine. Abraded areas of the cornea should remain highlighted with fluorescein.

**NOTE:** Rivulets of fluorescein (Seidel sign) tracking from a puncture site indicate an unsuspected penetration of the globe and require ophthalmologic consultation.

- 7. Make a drawing of the cornea for later reference, detailing the area(s) of abnormality.
- 8. If no cause of symptoms is found or if vertical streaking is found on the cornea, suspect an embedded conjunctival foreign body in the eyelid and examine the entire conjunctiva under cobalt-blue light. Keep in mind that fluorescein is taken up by mucus on the conjunctiva; therefore fluorescein staining with a conjunctival injury is less specific than with a corneal injury.
- 9. At this point, if no cause for the symptoms can be found, the eye should be examined under a slit lamp (see Chapter 67, Slit-Lamp Examination). A slit lamp is helpful when a plain fluorescein examination is nondiagnostic. For deep, dendritic, or central ulcerations or for ulcerations in which infection is suspected (i.e., if there is clouding of the cornea or a purulent discharge), the patient should be referred to an ophthalmologist (Fig. 66-4).

**Figure 66-4** Corneal defect staining patterns for specific injuries. **A,** Typical abrasion. **B,** Abrasion around a corneal foreign body. **C,** Abrasion from a conjunctival foreign body under the upper lid. **D,** Abrasion from excessive wearing of a contact lens. **E,** Ultraviolet exposure (resulting from sunlamp exposure, welding, or snow blindness). **F,** Herpetic dendritic keratitis.

### TREATMENT OF UNCOMPLICATED CORNEAL ABRASIONS

#### **Considerations**

Some clinicians working in the emergency department refer all corneal abrasions to ophthalmologists for follow-up. Others rely on their knowledge, skills, and experience to make decisions regarding referral. Knowing that the risk for permanent visual impairment is affected by the magnitude of several factors associated with the abrasion (including depth, size, location, and susceptibility to infection) can be helpful for clinicians when making their decision. Lacking the magnification available with a slit lamp, the depth of the abrasion is often difficult to assess, so referral should be considered. Referral should also be considered for suspected deep or large lesions or for those located centrally in the line of vision. One way to assess a borderline case is to wait until the follow-up examination the next day. The corneal epithelium is one of the fastest-healing areas of the body, and if considerable progress toward healing has not been made by the next day or if there are signs of infection (cloudiness of cornea or pus), the patient should be referred immediately.

#### **Equipment**

- Topical ophthalmic anesthetic.
- Isotonic irrigant (Dacriose, Ringer's lactate, sterile saline).
- Ophthalmic antibiotics (ointment is better lubricating and 6 to 10 times less expensive than drops): bacitracin 500 U/g ointment, ciprofloxacin 0.3% solution, erythromycin 0.5% ointment, gentamicin 0.3% ointment or solution, ofloxacin 0.3% solution, sulfacetamide 10% ointment or 10% solution, tobramycin 0.3% solution. Contact lenses wearers need an antipseudomonal antibiotic (e.g., ciprofloxacin, gentamicin, ofloxacin).
- (Optional) Cycloplegic, mydriatic drops, such as tropicamide 0.5% or 1% (Tropicacyl, Mydriacyl) or 0.5%, 1%, or 2% cyclopentolate (Cyclogyl, Pentolair), may be useful for pain control. Their duration of action ranges from hours to a day.
- (Optional) Sterile eyepatches and 1-inch (preferably nonallergenic) paper tape.

#### **Technique**

- With the patient in the supine position, irrigate the eye copiously with ophthalmic irrigant, with the patient's head turned laterally toward the affected side.
- 2. Instill one to two additional drops of local anesthetic.
- 3. Apply an antibiotic ointment or drops. For patients who wear contact lenses, an antipseudomonal antibiotic should be chosen (e.g., ciprofloxacin, gentamicin, ofloxacin). Even under the best of conditions, infection is a possibility because of the avascular nature of the cornea. Prophylaxis with antibiotics is important.

NOTE: In the past, eye patching was thought to decrease pain from a corneal abrasion by decreasing blinking and reducing eyelid induced trauma. By being a physical barrier, it was also thought to reduce the risk of infection. However, at least one meta-analysis and several subsequent randomized clinical trials have found no benefit to patching regarding either pain or healing. In fact, eye patching was the source of pain in 48% of patients in one study! In various trials, ophthalmic topical NSAIDs provided pain relief that was superior to patching. Furthermore, eye patching decreases oxygen delivery, increases moisture, and may increase the risk of infection.

As a result of this evidence, many clinicians no longer use eye patching. However, the technique for patching remains in this chapter as an option. Another option that has been studied, for

the busy patient who *must* have continuous use of both eyes, is to use a soft contact lens as a protectant barrier. As long as the *cause* of the abrasion was not a contact lens, use of a soft contact lens usually provides comfort and protection and should not impair healing. However, if a soft contact lens is used, the patient should be followed closely and warned for signs of infection.

- 4. Pain medication should be prescribed in an amount appropriate to the symptoms. However, additional local anesthetic should not be prescribed because it may retard corneal healing and cause corneal scarring. Topical ophthalmic NSAIDs such as ketorolac (Acular) or diclofenac (Voltaren) have been found to reduce pain by about 14% compared with placebo. A systematic review of the literature found that patients using ophthalmic NSAIDs may take fewer oral analgesics, return to work earlier, and take fewer narcotics.
- 5. In the past, mydriatics were thought to relieve the pain related to ciliary muscle spasm associated with any corneal abrasion. Although there is minimal evidence supporting this practice, it may be reasonable to use a mydriatic when there is obvious spasm, iritis, or irregularity of the pupil (these patients should also be referred to an ophthalmologist). It may also be reasonable to use a mydriatic when the patient presents with photophobia or significant eye discomfort.
- 6. Re-examine the eye in 24 hours using fluorescein and magnification. If the abrasion has healed, antibiotic ointment or drops should be used for an additional 3 days. If the defect is smaller, instill antibiotic ointment and examine again in 24 hours. If at any time during the follow-up corneal cloudiness or suppuration is seen, refer the patient to an ophthalmologist.
- 7. The visual acuity test should be repeated and documented just before the patient is discharged from care.
- 8. Tetanus immunity should be verified or provided.

**NOTE:** Abrasions resulting from fingernails or plant matter are notoriously slow to heal. Their progress should be followed patiently, just like any other abrasion, while observing for any signs of early infection.

9. (Optional) A double patch (pressure patch) can be used. Before patching, an ophthalmic ointment (as opposed to solution) should be applied. The first patch is then folded and the fold placed immediately under the upper brow (this adds padding and prevents opening of the eye). This patch is covered with the second patch.

With three to five strips of paper tape, secure the patches by taping from the middle of the forehead, across the eye, and toward the ear (Fig. 66-5).

If infection is suspected, an eyepatch is contraindicated. Also, abrasions from organic material have fungal potential, so they should not be patched. Abrasions due to contact lenses increase the risk of infection with *Pseudomonas* so they should not be patched. Do not use eyepatches on young children. There is the theoretical risk of permanently affecting the use of one eye or of making amblyopia worse. Very young children typically remove a patch anyway.

#### **Complications**

- Infection.
- Scarring (the highest morbidity occurs when the abrasion is near the central line of vision).
- Permanent visual impairment.
- Recurrent corneal erosion (symptoms include foreign body pain, ocular pain, decreased vision, photophobia, increased lacrimation on wakening, blepharospasm). Although the symptoms may be annoying, they do not interfere with activities in most patients.

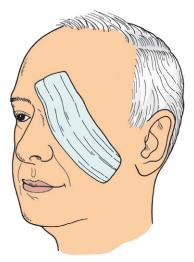

Figure 66-5 Pressure eyepatch.

#### **Postprocedure Patient Education**

Instruct the patient not to rub his or her eyes, especially upon wakening in the morning. Rubbing the eye may disrupt new layers of epithelializing cornea. Re-epithelialization can take weeks to complete. Inform the patient that the local anesthetic used during the examination will wear off in a few minutes to hours and that additional pain medication may be necessary. Topical ophthalmic NSAIDs have been found to be safe and somewhat effective. Moist compresses may be applied for some relief if the patient's eve has not been patched. Instruct the patient to return to the office daily until healed or if persistent or recurrent symptoms develop. If a mydriatic was used, inform the patient which one. Also inform the patient to tell any other clinician involved that a mydriatic was used, and which one, if he or she will be seen in another center or referred so that the clinician can know how long to expect the pupil to remain dilated. Instruct the patient not to overuse the affected eye, such as by watching television or reading for prolonged periods. This is especially true for children or anyone with a history of amblyopia. Although there is not a lot of evidence supporting such an intervention, if the abrasion is due to a contact lens, the patient probably should avoid contact lenses until the abrasion is completely healed. It is important to document the degree of healing observed during the discharge examination. Safety goggles or protective glasses should be emphasized if the abrasion was an occupational, exposure, or sports injury. If the eye is patched, the patient should not drive owing to the loss of depth perception. Even if the eye is not patched, the patient should not drive if there is loss of vision or depth perception until the injury heals.

### CORNEAL OR CONJUNCTIVAL FOREIGN BODY REMOVAL

#### **Indications**

Noninfected, small, recent corneal or conjunctival foreign body

#### **Contraindications**

The contraindications (those that should be referred to ophthalmology) are the same as those for "Fluorescein Examination of the Cornea and Conjunctiva," as well as the following:

 Signs or symptoms that suggest infection, such as edema and clouding of the cornea surrounding the foreign body, ulceration exceeding the size of the foreign body, or purulent discharge

- Large metal foreign body or foreign body with potential to cause a large rust ring (e.g., embedded in the cornea for longer than 24 hours)
- Deeply or centrally embedded foreign body or one that has healed and is covered by epithelium

#### **Equipment**

- Topical ophthalmic anesthetic
- Sterile cotton-tipped applicators
- Bright white and cobalt-blue light sources
- Magnification as previously listed (it may be necessary to have an assistant hold the magnifier to allow the operator to use both hands)
- Isotonic ophthalmic irrigant, such as Dacriose, Ringer's lactate, or sterile saline
- Snellen chart or equivalent visual acuity chart
- Sterile 18-gauge needle with small syringe
- Sterile dental burr or cornea drill (optional)

**NOTE:** Instead of an 18-gauge needle, a tuberculin syringe with a 26-gauge needle, a sterile eye spud, or a small, sterile chalazion curette may be substituted, depending on user experience.

#### **Preprocedure Patient Preparation**

Instruct the patient that it will be important to fix his or her gaze on a distant object, maintain that gaze, and hold the head motionless, regardless of what is seen or experienced. The patient will have the urge to blink, but it will be important to keep the eye open. Inform the patient that the eye will be numb from the local anesthetic, but that he or she may feel pressure during the procedure. The patient should know that you will need to touch him or her.

Advise the patient of possible complications and that referral may be necessary regardless of outcome. Some clinicians obtain signed informed consent.

#### **Technique**

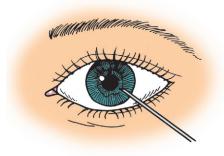

Controversy exists about the use of a swab or a spud to remove a corneal foreign body and whether this causes more damage. Only experienced users should consider a swab or spud, and they should use them only for a small foreign body. The swab will be more successful with a very recent, superficial foreign body. Irrigation alone is not usually successful unless the foreign object is very recent, consists of carbon, or is water soluble. The patient's tears would normally have already washed away anything that irrigation would remove.

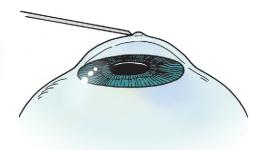

**NOTE:** Because there may be increased risk of damaging the cornea, it may be prudent to avoid significant corneal procedures in patients who have undergone laser-assisted in situ keratomileusis

(LASIK) procedure for nearsightedness. Clinicians should also examine patients who have undergone radial keratotomy very closely under magnification. The corneal incisions in these patients have been known to gape for 6 years postprocedure, and these can entrap a foreign body.

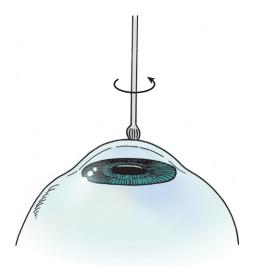

- 1. Record the patient's visual acuity.
- 2. With the patient supine, hold the eyelids apart with your thumb and index finger, and position the patient's head so that the foreign object is at the highest point on the eyeball. The patient should fix his or her gaze. For a conjunctival foreign body, the head should be positioned for maximal access.
- 3. Make an attempt to dislodge the object. Noting the controversy regarding swab or spud use, try to lift the object by lightly touching it with a cotton swab moistened with local anesthetic. This occasionally dislodges the particle. Never use any force to rub the cornea because this will dislodge the epithelium and cause a larger abrasion. The same maneuver can be attempted for a conjunctival foreign body.
- 4. To use a sterile needle, approach the object from a direction tangential to the eyeball, with the needle bevel upwards and the syringe held with a pencil grip (Fig. 66-6). Rest your hand on the patient's zygoma so that if the patient moves, your hand will move with the patient. Use the needle tip to lift the object gently from its bed. Several attempts may have to be made, but use of a slit lamp (see Chapter 67, Slit-Lamp Examination) or referral should be considered if further corneal damage is anticipated. If several attempts with a needle are unsuccessful, a spud or chalazion curette may be considered (again, noting the controversy discussed). For a conjunctival foreign body, the technique is the same; attempt to lift it from its bed with the same instruments. More vigorous force, if controlled, may be used on the conjunctiva.
- 5. After removal of the foreign body, if a residual corneal rust ring is found under magnification, it can occasionally be removed with the sterile needle alone. A cornea drill may also be considered. It should have a pressure-sensitive automatic shutoff to minimize corneal damage. Another published technique involves the use of a sterile dental burr held between the thumb and forefinger to approach the rust ring vertically (Fig. 66-7). After the burr has made one gentle rotation, re-examine the eye under magnification to verify complete removal of the ring. Rust is toxic to corneal epithelium and prevents healing; it may also cause night-time visual defects. If attempts to remove the rust ring are unsuccessful or if they will cause further damage to corneal epithelium, referral should be made for management under slit lamp magnification.

**NOTE:** Some experts suggest that use of a corneal drill or dental burr is contraindicated when the foreign body or rust ring is in the central line of vision. Instead, they recommend referral.

**Figure 66-6** Removal of a superficial corneal foreign body. Side view illustrates the thickness of the cornea relative to the beveled needle edge. The needle or eye spud should be held tangential to the cornea, and the object should be gently lifted off of the cornea

**Figure 66-7** Dental burr rotated once to remove corneal rust ring. Note vertical approach.

6. Retest and record the patient's visual acuity. The corneal defect that is present after removal of the foreign body should now be managed the same as a corneal abrasion.

#### **Postprocedure Patient Education**

Follow the guidelines for treatment of an uncomplicated corneal abrasion. If the object cannot be removed, the resultant rust ring is too large, or the patient is referred to an ophthalmologist for any other reason, the ophthalmologist should provide further patient education.

#### **Complications**

- Same as the complications associated with treatment of a routine corneal abrasion, except the risk of corneal scarring is higher
- Perforation of the cornea or globe
- Incomplete removal of a foreign body
- Failure to heal because of a retained rust ring, infection, or other causes

#### **CPT/BILLING CODES**

- 65205 Removal of foreign body, external eye; conjunctival superficial
- 65210 Removal of foreign body, external eye; conjunctival embedded (includes concretions), subconjunctival, or scleral nonperforating

- 65220 Removal of foreign body, external eye; corneal without slit
- 99070 Eye tray: supplies and materials (except spectacles) provided by physician over and above those that are usually included with the office visit or other services rendered (list drugs, trays, supplies, or materials provided)
- 99173 Screening test of visual acuity, quantitative, bilateral (e.g., Snellen chart)

#### **ICD-9-CM DIAGNOSTIC CODES**

- 360.60 Intraocular foreign body, unspecified
- 361.00 Retinal detachment with retinal defect, unspecified
- 364.00 Acute iritis
- 364.70 Adhesions of iris, unspecified
- 370.20 Superficial corneal keratitis without conjunctivitis
- 370.24 Photokeratitis
- 371.82 Corneal injury due to contact lens
- 918.1 Corneal abrasion
- 918.2 Superficial injury of conjunctiva
- 930.0 Corneal foreign body
- 930.1 Foreign body in conjunctival sac

# SLIT-LAMP EXAMINATION

Christopher J. Bigelow

The slit-lamp biomicroscope is used for a thorough evaluation of the eye as well as for diagnosis of various eye conditions. In short, the eyes remain in a fixed position while the light and microscope are independently moved and adjusted. As with any instrument, repeated use facilitates clinician comfort with the scope as well as his or her ability to obtain the desired or necessary information. With its many levers and knobs (Fig. 67-1), the slit lamp can be somewhat intimidating at first. However, after learning a few simple techniques, even the infrequent user should feel comfortable. Granted, not every primary care clinician's office has a slit lamp. However, if one is available, it can be an invaluable diagnostic opportunity that should not be missed because of lack of experience. Clinicians working in an urgent care center or emergency department would also benefit from knowing how to use a slit lamp. The goal of this chapter is to provide even the novice user with guidance for performing a useful and reproducible slit-lamp examination.

A slit lamp consists of both an illumination and an observation system (see Fig. 67-1). The light source is an incandescent lamp contained in the body of the instrument. Light from the lamp passes through a condenser, the slit mechanism, and an objective lens and is then reflected by an inclined mirror onto the patient's eye. When projected onto the globe, the slit beam of incandescent light creates an optical cross-section of the eye. The height and width of the beam (Fig. 67-2) can be adjusted with controls (often different on each slit lamp). It can be changed from a small pinpoint spot to a slit beam or made even wider for broad illumination. As the beam is narrowed, the scattered light from adjacent tissue is minimized, allowing greater

**Figure 67-1** A slit lamp and its optics. (From Solley WA, Broocker G: General eye exam. In Palay DA, Krachmer JH: Ophthalmology for the Primary Care Physician. St. Louis, CV Mosby, 1997, pp 1–22.)

detail to be seen in the cross-section. Beam sizes, their widths, and their usefulness are discussed in the "Technique" section. Light intensity can also be adjusted. In general, brighter illumination settings are better tolerated (e.g., less photophobia) with a short, narrow beam, whereas a long, wide beam is usually better tolerated with a lower-power illumination setting. The observation system is a microscope with a long working distance. Most slit lamps offer a choice of magnification between 5× and 50×. The necessary degree of magnification depends on the tissue being examined.

Use of the slit lamp is indicated in any situation where brighter illumination and increased magnification of the lids, conjunctiva, or anterior segment structures (e.g., cornea, iris, lens) would be helpful. If desired, the clinician could use a slit lamp for most examinations of the eye. With increased magnification, oblique illumination, and a stereoscopic view, a much better evaluation of lesions can be obtained, especially their depth. Attachments are also available to perform applanation (Goldmann) tonometry (see Chapter 68, Tonometry), which is considered the most accurate form of tonometry. In addition, high-powered lenses are available for most slit lamps to allow visualization of the posterior structures (e.g., retina, optic nerve).

#### **INDICATIONS**

- Need for bright illumination or magnification of lids, conjunctiva, or anterior segment structures (e.g., chronic blepharitis, keratitis, iritis).
- Same indications as for routine fluorescein examination or for foreign body removal (see Chapter 66, Corneal Abrasions and Removal of Corneal or Conjunctival Foreign Bodies). If a slit lamp is available, it will enhance the techniques found in that chapter.

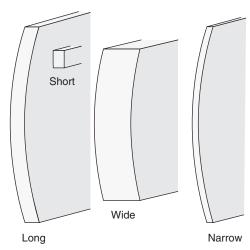

Figure 67-2 Different dimensions of the slit-lamp beam.

- Patient with a foreign body sensation and routine fluorescein examination is negative, or when the routine fluorescein examination is inconclusive or unsuccessful.
- Suspected deep or large abrasions or those centrally located in the line of vision on fluorescein examination. Such lesions increase the risk of vision loss and should be evaluated thoroughly and followed clinically with a slit lamp.
- After several unsuccessful attempts at removing a corneal foreign body in the standard fashion, before additional trauma is inflicted on the cornea, the foreign body and cornea should be evaluated under a slit lamp. It may also be necessary to remove the foreign body with slit-lamp guidance.
- When routine fluorescein examination is relatively contraindicated (e.g., when there is long-standing [>24 hours] inflammation, possible perforation). The presence of iritis, photophobia, or ciliary blush may indicate long-standing inflammation, or it may be the result of an intraocular foreign body or a more serious injury. If the etiology is not evident with a slit-lamp examination, the patient should be referred to an ophthalmologist.
- Recent eye trauma (e.g., to exclude perforation).

#### **CONTRAINDICATIONS**

After urgent care has been provided, patients with the following symptoms should be referred to an ophthalmologist:

 Suspected high-velocity injury to the eye (e.g., patients exposed to metal hammering or heavy machinery): although a slit lamp may diagnose a perforation, it is possible for high-speed metallic or nonmetallic fragments to penetrate the globe with unnoticeable damage to the cornea. Although there may be minimal symptoms, significant internal damage may have occurred. A hyphema, lens opacification, an abnormal anterior chamber examination, or an irregularity of the pupil may suggest that the globe has been penetrated. Orbital radiographs may confirm a metal foreign body.

**NOTE:** A pressure patch is contraindicated in a penetration injury of the globe. Also, for complex lid lacerations, a nonpressure protective eye shield should be applied before referral (see Chapter 66, Corneal Abrasions and Removal of Corneal or Conjunctival Foreign Bodies, Fig. 66-1).

- Exposure to caustic or acidic media: urgent management includes copious irrigation, which should continue for at least 15 minutes. (It can begin at home with tap water from a shower or hose.)
- Other chemical exposure if the clinician is not knowledgeable about its management after contacting a Poison Control Center.
- Ruptured globe.
- An uncooperative patient. (Mild sedation for infants may be helpful; see Chapter 7, Pediatric Sedation and Analgesia.)
- Foreign body removal if there are signs or symptoms that suggest infection (e.g., edema and clouding of the cornea surrounding the foreign body, ulceration exceeding the size of the foreign body, or purulent discharge). If infection is suspected, patching is contraindicated and referral is necessary.
- Large metal foreign bodies or those with potential to cause a large rust ring (i.e., those that have been embedded in the cornea for longer than 24 hours).
- Apparently deeply or centrally embedded foreign bodies.

**NOTE:** For these contraindications, although the slit lamp may be helpful for a primary care clinician, management by an ophthalmologist is the usual care.

#### **EQUIPMENT**

 Topical ophthalmic anesthetic, such as 0.5% proparacaine (Alcaine or Ophthaine) or 0.5% tetracaine (Pontocaine), unless contraindicated (e.g., ruptured globe or allergy to local anesthetics).

- Sterile fluorescein sodium strips. (Because fluorescein is incompatible with preservatives effective against *Pseudomonas* or *Proteus*, multidose dropper bottles of fluorescein solution should not be used. An inoculation of abraded corneal epithelium with either of these bacteria could cause infection, scarring, or permanent blindness.)
- Sterile cotton-tipped applicators.
- Isopropyl alcohol swab.
- Isotonic ophthalmic irrigant (e.g., sterile saline, Dacriose).
- Slit lamp: the two most common slit lamps in use are manufactured by Haag-Streit and Zeiss (see "Suppliers" section).

#### PREPROCEDURE PATIENT PREPARATION

Patients should be informed about the indication(s) for and alternatives to the slit-lamp examination. Once their chins are placed on the scope, patients should be asked to get into a comfortable position that can be maintained for a while. They should be instructed to breathe normally and, especially children, asked to remain as still as possible. Children may need assistance with holding still. Patients should know to blink normally unless their eyes are being held open by the examiner or they are asked to hold their eyes open. They should be aware of the need for the examiner to touch their faces and even to pull on their eyelids. It should be explained that the room is going to be darkened and that a bright light can be expected, especially if the pupil is dilated. Reassurance that this bright light will not cause permanent visual damage is usually appreciated. In fact, patients should be told that the reason for using this bright light (in most cases) is to prevent permanent damage to their vision.

The patient needs to know that he or she will be asked to direct his or her vision to certain locations and that eyedrops or dye may be necessary to enhance the examination. Before fluorescein is instilled, the patient should remove contact lenses and be warned that objects in his or her vision may temporarily appear yellow. Tears may also remain yellow for a short time after the examination and might stain skin or clothing, at least temporarily, so they should avoid rubbing their eyes or drying their tears on something that might stain. Before topical anesthetic is instilled, the patient should be warned that it may cause a burning sensation until the eye becomes numb.

#### **TECHNIQUE**

1. Clinicians should be familiar with the anatomy of the external eye before evaluation with a slit lamp (Fig. 67-3). For the novice or infrequent user of a slit lamp, it may also be helpful to get comfortable with the instrument before the patient is in the room. Learn to locate and loosen the locking nut for the mechanical assembly. Practice with the joystick, turn the knobs, and watch the results. The clinician may then benefit from focusing the slit lamp on an object or the skin on his or her hand to gain some sense of perspective. In an urgent care center or emergency department, practicing before the patient is in the room may be important because the slit lamp is often left in complete disarray by others.

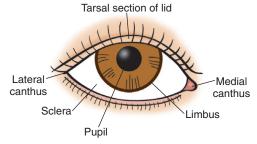

Figure 67-3 External anatomy of the eye.

- 2. Proper patient positioning is absolutely essential for a satisfactory examination. Both the patient and the examiner should be comfortable. An improperly positioned patient is more likely to move backward and out of focus. He or she is also less likely to maintain positioning for extended periods of time. The patient is seated during the examination. Clean the chin rest with an alcohol swab. The examination chair height should be such that the patient can easily place his or her chin on the adjustable chin rest and forehead against the headrest. Some slit lamps have an eye level marker to assist in gauging head positioning. If the patient is unable to place his or her forehead against the headrest, either elevate the chair or lower the chin rest. If the patient is not positioned against the headrest, it will be difficult to focus on deeper ocular structures. This common mistake often causes a great deal of frustration for the novice slit-lamp user. After the patient is positioned, loss of focus may indicate that he or she has moved his or her head backward. It should be repositioned. Small children should sit in the chair on their knees, stand up on the footrest, or sit in their parent's lap.
- 3. Examiner positioning is also important. The clinician should be able to reach the patient's eye comfortably and easily rest an elbow on the slit-lamp table. Such a position is important if the eyelids need to be manipulated or for holding instruments used in foreign body removal. The examiner should also be seated comfortably in the chair so that his or her eyes easily reach the eyepiece without leaning forward. This description may seem overly simplistic, but many a novice slit-lamp examiner looks like a baseball catcher coming up from a crouch. This is not a position that can be maintained for very long.
- 4. Turn on the power to the lamp (the switch is usually located on the left lower side, just under the table base), and select anywhere from a low power (preserves bulb life the longest) to the next-to-highest power illumination setting. The illumination power setting rheostat is usually part of the power switch or located nearby. The eyepieces can then be adjusted to correct the clinician's refractive error, although it is often simpler for the clinician to set the eyepieces at zero (1×) and wear his or her spectacles or contact lenses. Once the eyepieces are adjusted, the interpupillary distance is set. After this adjustment, no further manipulation of the eyepieces should be necessary. Magnification can be changed with a knob found anterior to the eyepieces on some slit lamps, or by shifting a lever found below the eyepieces on other models.
- 5. After positioning and eyepiece adjustment, darken the examination room as much as possible. The eyepieces (and thus the examiner) should remain perpendicular to the chin rest throughout the examination. The light source, not the oculars, should be moved to facilitate viewing. Move the light source vertically by using the control lever located at the base of the slit lamp. Horizontal movement is accomplished by moving the swing arm with the examiner's other hand. Position the slit beam at an oblique angle, starting at the temporal side of each eye and moving the light nasally. Beware when moving the light source from the temporal side of the eye: from this position, if the examiner is not careful, the patient's nose is often struck by the mirror or light source. To view the nasal portion of an eye, have the patient gaze temporally on that side, which should bring the desired area into focus.
- 6. The depth of focus is adjusted by moving the slit lamp backward and forward. Focusing is typically accomplished at the same time as vertical positioning with the joystick. Remember to examine both eyes, even if the symptoms are monocular. The "normal" eye can be used for comparison with any pathology in the other eye.
- 7. At the start of the examination, the patient should be instructed to look toward the examiner's ear opposite to the eye being examined (i.e., the patient looks at the examiner's left ear while the right eye is being examined). Some slit lamps have a fixation

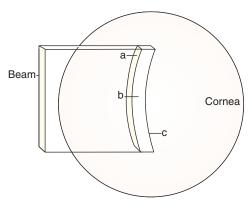

- light to direct the patient's gaze, but it is often simpler to instruct the patient to focus on a larger, nonmoving object such as the examiner's ear.
- 8. Evaluation of the ocular structures has already begun with a focused history, the measurement of visual acuity in both eyes, and a gross handlight examination of the eyelid skin and surrounding structures. The slit-lamp examination should then proceed in a systematic manner from external (lids and lashes) to internal (vitreous). Failing to be systematic can cause the examiner to get caught up in the fine detail that the slit lamp provides. As a result, the examiner may "miss the forest for the trees."
- 9. Choose the white light beam filter lens. A long, wide beam is useful for scanning tissues such as the lids and lashes. For these structures, a low-power magnification (e.g., 10× to 16×) should be adequate.

**NOTE:** Avoid focusing the light into the pupil for an extended period. This can be very uncomfortable for the patient and may result in injury.

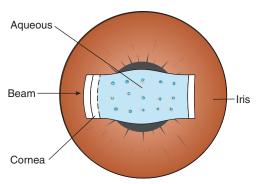

- Observe the general appearance of the lid margin; the lid's color, position, and vascularity; and any meibomian gland openings. Thickening, crusting, and erythema of the eyelid margins are consistent with blepharitis. Examine the lashes and eyebrows for the presence of inflammation, scaling, or elevated or ulcerated lesions. Also examine the lashes for evidence of lid debris and for missing or additional lashes. Scan for the misdirection of lashes (trichiasis), which can cause a severe foreign body sensation in an otherwise normally positioned lid. If there are only a few misdirected eyelashes, pluck them with fine forceps. If there are many, the patient should be referred for electrolysis (see Chapter 39. Epilation of Isolated Hairs [Including Trichiasis]) of the roots. Also evaluate lid position for being turned in (entropion) or out (ectropion). Note discrete changes in lid pigmentation.
- Examination of the lower lid is aided by having the patient look up while pulling the lower lid down with your index finger. This exposure provides a good view of the posterior lid margin and the lower palpebral conjunctiva. Eversion of the upper lid is necessary to properly examine the upper palpebral conjunctiva (e.g., to exclude foreign bodies). Lid eversion can be performed by having the patient close his or her eyes and look down (see Chapter 66, Corneal Abrasions and Removal of Corneal or Conjunctival Foreign Bodies, Fig. 66-3). Grasp the upper lid margin gently between thumb and index finger. A cotton-tipped swab is then placed about 15 mm from the lid margin. The lid is then moved out, up, and over the cotton-tipped swab. A drop of local anesthetic often enhances patient comfort with this procedure. Carefully examine the few millimeters proximal to the lid margin. This is a common location for small foreign bodies missed on the routine examination.
- 10. A long, wide beam is also used to examine the conjunctiva. Low-power magnification (e.g., 10× to 16×) should be adequate. The examiner gently separates the eyelids with the opposite hand while the patient is asked to look in all directions of gaze. The conjunctiva is normally a transparent tissue with the white sclera visible beneath. Occasionally, there are slightly elevated, yellow lesions at the 3- and 9-o'clock positions at the limbus (edge of cornea) called *pinguecula*. These benign lesions are more common with advancing age. Areas of pigmentation of the conjunctiva can also be seen. These are commonly benign nevi, most often translucent and flat. For irregularly shaped or pigmented lesions suspect for melanoma, the patient should be referred to an ophthalmologist.
- 11. A long, narrow beam, which produces an optical cross-section, is usually best for examining the cornea. Higher-power

magnification (e.g., >20×) may be useful when examining the cornea in minute detail. Within this cross-section, the epithelium or tear film is seen as the most anterior band. The stroma can be seen as the large middle layer, and the posterior band represents the endothelium (Fig. 67-4). The examiner brings the slit-lamp beam across the cornea from the temporal to the nasal limbus while paying attention to the regularity of the corneal surface. Any disruption in the corneal surface such as an abrasion should be easily noted as an irregular, distorted, or dulled light reflex. When the light is shone from a lateral position, it produces greater shadows, which in turn enhances the ability to determine the depth and texture of corneal lesions.

- One way of screening for a corneal lesion or foreign object is to use limbal scatter. To do this, light is directed from the laterally placed scope to the closest portion of the limbus. The cornea then simulates a fiberoptic element, and light is transmitted through the cornea medially to the limbus on the other side. A lesion or foreign body in the cornea should cause light to backscatter; consequently, the lesion should be seen clearly against the dark pupillary background.
- Deeper focus allows examination of the corneal stroma, which makes up 90% of the corneal tissue. A narrow slit beam allows for accurate determination of the depth of either a foreign body or a penetrating injury involving this area. Opacities or haze may be noted, both of which are indicative of previous trauma, infection, or inflammation. Old lesions tend to be more circumscribed, whereas an active keratitis usually produces a diffuse pattern of corneal haze.
- The endothelium is visible as the posterior line in the optical section. Abnormalities may present either as folds in the endothelium or as changes that resemble the surface of a golf ball called *corneal guttae*. Both of these changes may be indicative of endothelial cell loss.
- 12. The anterior chamber is the space between the corneal endothelium and the iris. Continuing to use a narrow beam, gauge the anterior chamber depth by estimating the distance between the corneal endothelium and the front surface of the iris. This distance is normally 3 mm or more. When shining from the temporal to the nasal side, a normal anterior chamber will allow this narrow light beam to project evenly from side to side. A narrowed anterior chamber will have a lighted temporal side and a narrowed nasal side.
- 13. The aqueous humor is normally clear, with light passing through it without change. To examine the aqueous humor for the presence of cells or flare, a short (3 or 4 mm), narrow beam with bright illumination and high magnification (e.g., >20× to 30×) should be used. Cells in the aqueous humor may indicate inflammation (iritis) or hemorrhage (hyphema). While keeping the beam centered on the pupil, any white (i.e., white blood cells, indicating iritis) or red (i.e., red blood cells, indicating a

**Figure 67-4** Optical cross-section of the cornea: Corneal epithelium (a); corneal stroma (b); corneal endothelium (c).

**Figure 67-5** Optical cross-section of the anterior chamber showing cell and flare.

hyphema) specks will be highlighted against the dark pupillary background. Protein in the aqueous humor (i.e., intraocular inflammation) causes a visible flare (Tyndall effect). This effect is similar to that seen when shining a flashlight through smoke (Fig. 67-5). Take care to examine the lower aspect of the anterior chamber because cells and inflammatory products tend to settle in this part of the eye and may form a meniscus when the patient is seated upright.

- 14. The iris has numerous crypts that should be plainly visible with the slit lamp. Nevi, surgical openings, neovascularization, atrophy, tears, or abnormally pigmented lesions may be seen with magnification. If the iris is scarred to the lens (posterior synechiae) or cornea (anterior synechiae), it should be noted. Of interest in those patients who have undergone cataract extraction, a tremulousness of the iris called *iridodonesis* is often seen. It is caused by removal of the support usually provided by the lens
- 15. Next, use a long, narrow slit beam to examine the layers of the lens. Dilating the pupil allows for the most thorough evaluation of the lens. Any opacity in the crystalline lens is called a *cataract*. The slit beam passes through multiple layers from anterior to posterior: anterior capsule, anterior cortex, nucleus, posterior cortex, and posterior capsule (Fig. 67-6). Cortical cataracts resemble spokes radiating from the lens equator. Nuclear cataracts are central and are often seen as a yellow or amber hue discoloring the normally clear lens. Posterior subcapsular cataracts often appear as clustered punctate vacuoles. These can be seen either directly or with retroillumination.

Retroillumination uses the red reflex and will often provide a striking view of a lens opacity, especially through a dilated pupil. The slit beam is directed parallel to the visual axis to either the nasal or temporal side of the lens. The examiner then views the red reflex, which is the light reflected off the retina and back through the lens. Against this red background, lens opacities such as capsular cataracts are prominently displayed.

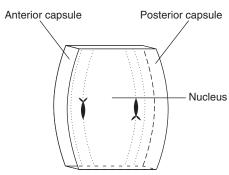

Figure 67-6 Optical cross-section of the lens.

- 16. After examining the posterior lens capsule, examine the anterior vitreous humor. Normally, the vitreous humor is a relatively clear fluid with minimal cellular material. If cellular material is noted, refer the patient to an ophthalmologist. Gross vitreous opacities, such as floaters, can also be seen with the slit beam.
- 17. At this point, if a corneal abrasion is suspected but not yet seen, a fluorescein strip should be used. It will stain areas of absent epithelium bright green when viewed with a cobalt-blue light filter. A wider slit beam is better tolerated by patients (i.e., causes less photophobia) if it is blue. (For instilling fluorescein, see Chapter 66, Corneal Abrasions and Removal of Corneal or Conjunctival Foreign Bodies.) Be careful to use minimal amounts of fluorescein to avoid flooding the eye and obscuring the abnormal epithelium. (Also, avoid staining the patient's skin and clothing with fluorescein!) Avoid touching the cornea directly with a fluorescein strip because this may result in an iatrogenically stained cornea. If either of these occurs, have the patient blink, blot the excess fluorescein away, and then reexamine. If the eye is still flooded, flush it with ophthalmic saline and again have the patient blot away the excess. The fluorescein examination is usually performed after the remainder of the eye has been examined with the slit lamp to avoid any "light scatter" that could be caused by fluorescein adsorbed to a corneal abrasion.
- 18. Using special lenses, often through a dilated pupil, the vitreous body, retina, and optic nerve can also be viewed with a slit lamp. For example, a Hruby lens can be attached by inserting the lens spindle into the groove of the lens guide plate on the slit lamp. A handheld lens positioned in front of the patient's eye can also be used in the same manner. When using a lens, the slit beam is positioned parallel to the visual axis. (Distracting light reflections off the lenses can often be resolved by tilting the lens slightly.) The posterior structures of the eye can then be examined. This part of the examination should probably not be performed if the patient has an iritis or a corneal abrasion because of the associated severe photophobia.

#### POSTPROCEDURE PATIENT EDUCATION

The findings should be discussed with the patient, as well as any needed postprocedure care. Any necessary referrals should be made. For corneal foreign bodies or abrasions, see Chapter 66, Corneal Abrasions and Removal of Corneal or Conjunctival Foreign Bodies, for management and postprocedure patient information.

#### **CPT/BILLING CODES**

- 65222 Removal of foreign body, external eye; corneal with slit
- 92002 Ophthalmologic services: medical examination and evaluation with initiation of diagnostic and treatment program; intermediate, new patient

92012 Intermediate, established patient

NOTE: Intermediate examination includes biomicroscopy.

Eye tray: supplies and materials (except spectacles) provided by physician over and above those that are usually included with the office visit or other services rendered (list drugs, trays, supplies, or materials provided)

#### **ICD-9-CM DIAGNOSTIC CODES**

## **TONOMETRY**

Deepa A. Vasudevan • Grant C. Fowler

Tonometry is used to detect increased intraocular pressure, which is common in patients at risk for glaucoma. Glaucoma is actually caused by a group of conditions, all of which can lead to optic nerve damage and a loss of visual function. More than 2 million persons in the United States are estimated to have some degree of blindness caused by glaucoma. It is the third most common cause of blindness, and its incidence increases with age. Despite the fact that most blindness caused by glaucoma is preventable, or at least able to be delayed, there are estimates that less than half of patients with glaucoma have been diagnosed. Tonometry remains one of the easiest methods of screening for glaucoma; however, patients with glaucoma can have normal intraocular pressures and, vice versa, not all patients with increased intraocular pressures have glaucoma. Researchers are currently pursuing other risk factors associated with glaucomatous changes in the eye to develop additional practical screening techniques. When this succeeds, glaucoma will be more readily diagnosed, even in those with normal intraocular pressure. Until then, tonometry, in combination with funduscopic examination and visual field testing, is the most sensitive and specific method for detection of glaucomatous changes in the eye. Patients at high risk for glaucoma should be screened with all three.

There are three basic types of tonometry. Impression tonometry measures the depth of the impression produced on the ocular wall by a given force, and the Schiøtz tonometer uses this method. Noncontact/air-puff tonometry, originally considered the least accurate and therefore designed for screening (especially for children), has turned out to be fairly accurate even when compared with applanation tonometry, the "gold" standard. Applanation (Goldmann) tonometry measures the force necessary to flatten an area of the cornea. Because applanation tonometry is more accurate than Schiøtz tonometry, most optometrists and ophthalmologists use this technique; however, it requires the ability to use a slit lamp (see Chapter 67, Slit-Lamp Examination). Consequently, the Schiøtz tonometer is still the standard for measuring intraocular pressure in the offices of primary care clinicians, in urgent care centers, and in emergency departments. The Schiøtz tonometer is also less expensive (about \$300). Many urgent care centers and emergency departments also now have available a hand-held portable device (e.g., Tono-Pen; Reichert, Inc., Depew, NY) that uses applanation technology, although it is somewhat more expensive (about \$3000) than the Schiøtz tonometer. Regardless of the method of tonometry, the clinician may recommend other tests or a referral if the initial test result is abnormal. This chapter discusses the techniques used in impression (Schiøtz and Tono-Pen), and applanation (Goldmann) tonometry.

#### **INDICATIONS**

#### Screening Those with Risk Factors

- Age older than 45 years (>35 years in African Americans).
- Family history of glaucoma (fourfold to ninefold increased risk).
- African Americans (fourfold to sixfold higher risk than whites).

- Hispanics age older than 60 years.
- Asian Americans (increased risk of angle-closure glaucoma, but this causes <10% of glaucoma).</li>
- Diabetes mellitus.
- Hypertension.
- Decreased visual acuity (myopia or hyperopia).
- Central corneal thickness less than 0.5 mm.
- Prior injury: blunt or penetrating trauma, eye surgery, eye inflammation (e.g., uveitis) can cause glaucoma acutely or years later.
- Prior or current medications: use of corticosteroids (including high-dose inhaled corticosteroids), mydriatics, phenothiazines, and sympathomimetics can precipitate glaucoma.

#### **Diagnosis**

 Ocular pain (especially if associated with signs or symptoms of angle-closure glaucoma such as acute-onset red eye, cloudy or smoky cornea, fixed mid-position pupil, blurry vision, halos around lights, nausea and vomiting, frontal headache)

**NOTE:** Patients with angle-closure glaucoma may complain more about nausea and vomiting than eye symptoms.

- Red eye (especially if associated with signs or symptoms of angleclosure glaucoma)
- History of visual field loss

#### **Determining Baseline Intraocular Pressure**

- Uveitis: patients with iritis or uveitis can develop both open- and closed-angle glaucoma. Corticosteroid treatment of uveitis can also cause glaucoma.
- After blunt ocular trauma: patients with hyphema often have an acute rise in intraocular pressure.
- Orbital fracture: an intraocular pressure greater than 22 mm Hg or a difference greater than 3 mm Hg between eyes is a reasonable marker for ocular injury in the patient with an orbital fracture.

#### **CONTRAINDICATIONS**

- Eye infection (Although Tono-Pen can be used because it uses disposable tip covers, noncontact tonometry may be preferred.)
- Corneal abrasion (Although Tono-Pen can be used in another area of the cornea, tonometry is commonly deferred until a subsequent visit.)
- Recent eye trauma (Tono-Pen/Schiøtz tonometry should not be performed in patients with suspected penetrating ocular injury; pressure on the globe can result in extrusion of intraocular contents. Slit-lamp examination should be performed to exclude perforation.)
- Patients who cannot keep their eyes still or open (Schiøtz and applanation tonometry cannot be used in patients with severe eyelid swelling or those unable to open their eyes; however, the Tono-Pen can sometimes be used.)

#### **EQUIPMENT**

- Topical ophthalmic anesthetic drops, such as proparacaine hydrochloride 0.5% or tetracaine 7%
- Gloves, mask, goggles (whatever is needed to follow universal blood and body fluid precautions)
- For Schiøtz: Schiøtz tonometer kit (each kit contains the tonometer, three plunger weights, a concave test block, conversion tables, pipe cleaners, and instructions for care)
- For Tono-Pen: Tono-Pen unit, condom-style disposable tip covers, optical-grade canned air for cleaning
- For applanation: Slit lamp with Goldmann applanation device attached, sterile fluorescein strips

#### PREPROCEDURE PATIENT PREPARATION

Explain the reason for measuring the intraocular pressure with the tonometer (e.g., presence of risk factors, symptoms, or positive physical findings). Briefly explain the procedure as well as the fact that this test only detects increased intraocular pressure. The patient should know that anesthetic ophthalmic drops may sting a little as they are instilled. The patient should also know that having normal intraocular pressures does not completely exclude glaucoma. If glaucoma is suspected, even with normal intraocular pressures, tonometry should be combined with the other tests mentioned previously.

#### **TECHNIQUE**

#### Schiøtz or Tono-Pen

- Check and record the patient's visual acuity. Examine the eyes. Immediately after the funduscopic examination, place two drops of topical ophthalmic anesthetic in each eye. (The anesthetic will have time to take effect while you prepare the tonometer.) The clinician should follow universal blood and body fluid precautions.
- 2. Assemble the Schiøtz tonometer with the 5.5-g weight in place, and test for accuracy on the convex metal test block (Fig. 68-1). The Schiøtz tonometer is precalibrated by the manufacturer and must be returned for repair if it does not read "0" when resting

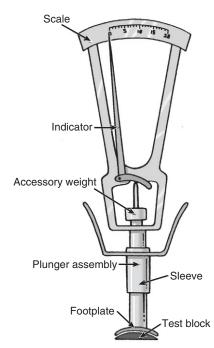

Figure 68-I Schiøtz tonometer.

**Figure 68-2** Hand-held tonometer (Tono-Pen XL). (Courtesy of Reichert, Inc., Depew, NY.)

on the test block. The Tono-Pen (Fig. 68-2) should also be calibrated before each use. Turn the transducer tip straight down and push the operation button twice within 1.5 seconds. It will beep and the liquid crystal display (LCD) will read "CAL." Although it may take up to 15 seconds, the Tono-Pen will then beep and display "UP." Immediately invert the tip straight upward, and if it is functioning properly, it should beep again and display "Good" in the LCD, which means it is calibrated. It is now ready for use, so the tip should be covered with a disposable cover.

**NOTE:** Beware of latex allergy in patients if latex Tono-Pen tip covers are being used.

Press the operation button again, and the instrument will display "[8.8.8.8]" followed by a single row of dashes and then a double row of dashes followed by a beep. Proceed with obtaining intraocular pressure readings within 15 seconds.

NOTE: Any time the operation button is depressed twice within 1.5 seconds, the instrument will attempt to calibrate and will display "CAL." While attempting to calibrate, if "Bad" is displayed in the LCD, repeat the process. If further attempts are unsuccessful, press the RESET button and repeat the process. If still unsuccessful, use optical-grade canned air to clean the probe tip for about 2 seconds, wait 3 minutes for the instrument to stabilize thermally, and then repeat the calibration process. If still not working, the batteries should be replaced and the process repeated. ("Lob" on the display also indicates low batteries.) Further unsuccessful attempts to calibrate warrant a call to technical support (1-800-866-6736 [TONO-PEN], www.tonopen.com, or see the supplier information in Appendix D).

- 3. For Schiøtz tonometry, have the patient lie on a table in the supine position and keep both eyes wide open. Ask the patient to relax and fix his or her gaze on a spot on the ceiling, with the line of vision perpendicular to the table. Retract the lids of the eve against the bony margin of the orbit with one hand, being careful to touch only the orbital margin because pressure directed into the orbit will cause the tonometer reading to be falsely elevated. Hold the tonometer by its handles with the thumb and middle finger of the other hand. After the patient has relaxed from the involuntary muscle contraction that occurs when the tonometer is first placed in his or her line of sight, center the foot plate of the tonometer over the cornea and gently lower the tonometer until it is resting on the cornea (Fig. 68-3). The indicator will come to rest at a position to the right of 0. The tonometer should be perpendicular to the cornea in a vertical position. Record the scale reading. If it is less than 4, repeat the reading because this indicates an elevated intraocular pressure. Perform another reading after adding the 7.5- or 10-g weight, as necessary, to obtain a scale reading between 4 and 8. Convert the scale reading to millimeters of mercury using the calibration scale included with the kit (Table 68-1). Record the intraocular pressure in the patient's chart. If the intraocular pressure in the other eye is going to be measured, immediately clean the foot plate with an alcohol swab and allow it to air dry for 1 to 2
- 4. If the Tono-Pen is used, the patient can be in any position. However, the head should be supported so that the patient cannot pull away when the Tono-Pen is placed in his or her line of vision. Have the patient fix his or her line of vision by looking straight ahead.

Figure 68-3 Examination with the Schiøtz tonometer.

TABLE 68-1 Tonometer	Sample C	Calibration S	cale for Schi	ðtz.
Scale	Intraocular Pressure (mm Hg) by Plunger Load			
Reading	5.5 g	7.5 g	10.0 g	15.0 g

From Schiøtz Tonometer Kit literature, courtesy of Gulden Ophthalmics, Elkins Park, Pennsylvania.

**NOTE:** Regardless of technique used, to assist patients in fixing their gaze, ask them to extend an arm straight upward or out and to stare at their thumbnail placed over a spot on the wall or ceiling.

5. The clinician should consider bracing the heel of his or her hand on the patient's cheek for stability and then touching the tip of the Tono-Pen lightly to the central cornea directly over the pupil (the cornea does not need to be indented; indentation may lead to inaccurate readings). If the cornea is abraded over the pupil, touch the Tono-Pen to the cornea elsewhere. While holding the Tono-Pen perpendicular to the corneal surface, tap the cornea lightly several times. The Tono-Pen will chirp after each valid intraocular pressure reading is obtained. After four valid readings, the Tono-Pen will sound a final beep and display a mean intraocular pressure (mm Hg) with a horizontal line under it on the LCD. The statistical reliability of the measurement is also displayed, and if the reliability measure (standard deviation) is 20% or higher, a repeat measurement is recommended. Likewise, a single row of dashes in the LCD indicates an insufficient number of valid readings were collected, so after pressing the operation button, additional measurements should be made. When a valid intraocular pressure is displayed, record it in the patient's chart.

**NOTE:** The tip of the Tono-Pen is a very sensitive probe that can be easily damaged, so it should never be touched by anything except a tip cover and then the cornea or the airflow from the optical-grade canned air when it needs to be cleaned.

6. Carefully clean the Schiøtz tonometer after each use to prevent transmission of disease. It can then be soaked in a special stand that soaks the tip only. A sterilizing solution that can eliminate human immunodeficiency virus should be used. Rinse carefully and allow to dry before using again. Alternatively, set the tonometer in an ultraviolet sterilizer stand. The tonometer should be disassembled at the end of each day and a pipe cleaner soaked with sterilizing solution run through the barrel to remove any debris. Accumulated debris could interfere with the motion of the plunger. Next, a dry pipe cleaner should be used to dry the barrel. The tonometer should not be oiled. If a Tono-Pen is used, it should not be immersed in fluids because the electronics will be damaged. Instead, the tip of the Tono-Pen should be cleaned of accumulated dust with optical-grade canned air; this step should be completed after it has been used for about 30 to 40 patients, or at least once a month. The tip cover should be changed after each use. A fresh tip cover should also be in place when the Tono-Pen is stored in the provided storage case. If the Tono-Pen is not going to be used for an extended period of time, the batteries should be removed.

#### **Applanation**

- Check and record the patient's visual acuity. Examine the eyes. Immediately after the funduscopic examination, place two drops of anesthetic in each eye. (The anesthetic will have time to take effect while you prepare the slit lamp and attached Goldmann tonometer tip.) The clinician should follow universal blood and body fluid precautions.
- 2. Stabilize the patient's head by putting his or her chin on the chin rest and placing the forehead firmly against the headrest of the slit lamp (see Chapter 67, Slit-Lamp Examination). Each eye should be stained with fluorescein and the patient then asked to gaze straight ahead. His or her vision can be further fixated by asking him or her to focus on the clinician's ear on the side opposite the eye being examined.
- 3. The slit lamp should be on low-power magnification, the light filter switched to cobalt blue, and the slit diaphragm opened completely. Angle the light arm at about 45 to 60 degrees to the

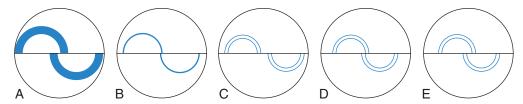

Figure 68-4 A, Semicircles too wide: excessive moisture. B, Semicircles too thin: excessive dryness. C, Intraocular pressure greater than knob setting (semicircles are correct width). D, Intraocular pressure equals knob setting (applied pressure). E, Intraocular pressure less than knob setting.

clinician's line of observation while shining the light on the plastic tonometer tip.

- 4. Set the pressure knob on the tonometer to 1 g (10 mm Hg). The patient should hold his or her eyes wide open and try to avoid blinking. The clinician may have to help the patient hold the lids open by applying pressure on the lids (only on the orbital rim).
- 5. Watching from the side (not through the slit lamp), the joystick should be used to move the tonometer tip up to the center of the patient's cornea, and then gentle contact is made. When contact is made, an immediate bluish glow should be noted all the way to the margin of the cornea. Avoid touching the lid margins with the tonometer tip because it will provoke blinking.
- 6. Through the slit lamp, the clinician should see two blue semicircles, each bordered by an arc of green light. These semicircles should be of equal extent above and below a horizontal dividing line. If the dividing line is not horizontal, the tonometer tip should be withdrawn and rotated on the holder until it is horizontal and reapplied to the cornea. If the semicircles extend beyond the illuminated field, there is too much pressure on the tonometer tip, so it should be backed away slightly from the eye.
- 7. The width of the arcs can be used to judge whether enough or excessive moisture is present. The width should be approximately 1/10 the diameter of the flattened surface contained within the arc. If the width is greater than 1/10 the diameter of the flattened area (Fig. 68-4A), too much moisture is present, either because of the tonometer tip being wet before application or because of excessive tears. The tip should be withdrawn from the patient's eye, dried, and reapplied. If the width of the arc is too narrow (Fig. 68-4B), the tear film has dried excessively. The tip should be withdrawn from the patient's eye and he or she should be asked to blink several times.
- 8. The blue semicircles and the surrounding green light will pulsate synchronously with the cardiac rate. If the intraocular pressure is greater than 10 mm Hg, the semicircles will not touch (Fig 68-4C). The clinician should turn the pressure knob up until the semicircles are touching (Fig. 68-4D). If the knob is turned up too far, the semicircles will overlap (Fig. 68-4E). Because the semicircles will move with cardiac pulsations, readings should be taken when the semicircles touch about midway between systole and diastole. In other words, when the knob pressure matches intraocular pressure, the semicircles should glide back and forth past each other through excursions of equal distance. If the width of the semicircles suddenly shrinks, either the patient has withdrawn from the scope or the instrument has been inadvertently backed away from the eye.
- 9. Record the intraocular pressure reading in the chart. Clean the tip of the tonometer with an alcohol swab immediately after use, and let it air dry for 1 to 2 minutes. Repeat the procedure on the contralateral eye if needed for comparison.

#### POSTPROCEDURE PATIENT EDUCATION

Routine prophylactic topical antibiotics are no longer prescribed after the procedure. The patient should be instructed to avoid rubbing, touching, or traumatizing the eyes for 1 or 2 hours after the

test to avoid injuring the cornea. A contact lens should not be worn until the eye regains sensation. Patients should be warned that an anesthetized eye is easily traumatized and they should call the clinician's office immediately if symptoms of a corneal abrasion occur. If the result is abnormal (increased intraocular pressure), follow-up care should be discussed. Most clinicians recommend consultation with an ophthalmologist if the pressure in either eye is greater than 20 mm Hg. Intraocular pressure less than 9 mm Hg with recent eye surgery or trauma should also be discussed with an ophthalmologist. Emergent consultation with an ophthalmologist or treatment should be considered if the pressure is greater than 26 mm Hg. Patients need to know the importance of follow-up; however, they should be aware that increased intraocular pressure does not always mean that they have glaucoma and, vice versa, that normal intraocular pressure does not always exclude glaucoma.

#### **COMPLICATIONS**

- Trauma to the cornea during tonometry is uncommon; however, a corneal abrasion can occur after the procedure while the cornea is still anesthetized.
- Infection can usually be avoided by properly cleaning the tonometer and using fresh Tono-Pen tip covers or applanation tips.
- Low-pressure glaucoma may be missed; therefore, patients with suspiciously cupped disks on ophthalmic examination should be referred.

#### **LIMITATIONS**

Falsely elevated intraocular pressure readings can be a normal variant, or they can be the result of an inflamed cornea, a scarred cornea, or pressure placed on the globe during the procedure. They can also occur with a thick or steeply curved cornea (Tono-Pen minimally affected). Falsely low measurements can be a normal variant, or they can result from high-grade myopia or rapidly repeated measurements.

#### **CPT/BILLING CODES**

Ophthalmological services constitute integrated services. Itemization of tonometry is not applicable.

- 92002 Ophthalmological services: medical examination and evaluation with initiation of diagnostic and treatment program; intermediate, new patient
- 92012 Ophthalmological services: medical examination and evaluation with initiation or continuation of diagnostic and treatment program; intermediate, established patient
- 92100 Serial tonometry (separate procedure) with multiple measurements of intraocular pressure over an extended time period with interpretation and report, same day (e.g., diurnal curve or medical treatment of acute elevation of intraocular pressure)
- 99173 Screening test of visual acuity, quantitative, bilateral (e.g., Snellen chart) (This cannot be used with 92002 or 92012)

# **AUDIOMETRY**

Gerald A. Amundsen

Hearing is measured according to its two main components: frequency/pitch and intensity/loudness. Audiometry is a procedure used to measure and graph an individual's hearing over a range of frequencies (measured in cycles per second [Hz, for Hertz]) at various intensity levels (measured in decibels [dB]). Although it is used frequently to test young children and the elderly (the groups at highest risk for hearing loss), audiometry is also an important component of any successful occupational hearing loss prevention program. In many instances, formal audiometry is performed by an audiologist; however, because screening audiometry is not a complex procedure and only a minimal amount of equipment is required, it is often performed by primary care clinicians. Even if not performing audiometry, primary care clinicians should have a basic understanding of not only the procedure but also the possible results.

An audiometer consists of a variable frequency oscillator that produces electrical impulses across the audible/perceptible frequencies, a transducer to convert the electrical impulses into sound or vibrations, and an attenuator to create variations in intensity. The device may be a stationary part of a designated testing facility or a portable unit with the flexibility to be used in a variety of settings. When sound is transmitted through headphones or an earpiece worn by the patient, and the patient responses are then recorded, an *air conduction audiogram* is produced. Air conduction audiometry evaluates both sensorineural and conductive hearing.

Sensorineural hearing refers to that produced by the cochlea of the inner ear, the auditory nerve, and the cochlear nuclei of the brain. There are both acquired and congenital causes of sensorineural hearing loss (Box 69-1). To test sensorineural hearing alone, a bone conduction audiogram is performed. With this procedure, similar to using a tuning fork when performing a physical examination, a bone conduction oscillator or vibrator is held against the mastoid process or forehead. Usually secured by a headband, the vibrator sets the skull into oscillation, producing a disturbance of the fluid in the cochlea. This disturbance is sensed by the cochlea and transmitted down the auditory nerve to the cochlear nuclei, all without use of the middle ear system. Results are graphed as the bone conduction audiogram. With pure sensorineural hearing loss, both air and bone conduction are impaired, and the impairments are about the same.

With air conduction hearing loss (usually due to middle or outer ear problems), air conduction is impaired but bone conduction is preserved. In the normal ear, the differences between the air and bone conduction thresholds, or the air—bone gap, should not exceed 10 dB. A gap larger than this indicates an air conduction problem (again, usually due to a middle or outer ear problem) as the source of hearing loss. Patients with air conduction hearing loss frequently respond to surgery; new surgical treatments for sensorineural hearing loss are also on the horizon. In many patients, hearing impairment is due to a combination, or a mixed hearing loss, and these also usually respond somewhat to surgery.

The symbols used on an audiogram (Fig. 69-1) have been standardized by the American Speech-Language Hearing Association (ASHA; www.ahsa.org). Traditionally, symbols representing the right ear were recorded in red, whereas results from the left ear were

recorded in blue. Because color is potentially lost in photocopying, different symbols specific to each ear are now used on most audiograms.

Frequency is represented on the horizontal axis of the graph from low to high, from left to right. Although the normal human ear is capable of hearing a range from 20 to 20,000 Hz, an audiogram usually tests the range most necessary for hearing and the understanding of speech (usually 250 to 8000 Hz). Intensity, the measurement of "loudness," is represented on the vertical or left axis of the graph, and usually ranges from 0 to 120 dB. Data points plotted on the graph represent the lowest decibel intensity that can be heard by the individual 50% of the time at each frequency, and this is the auditory threshold for that particular frequency.

Results are interpreted relative to 0 dB, or *audiometric zero*. *Audiometric zero* is defined as "normal" by the American National Standards Institute (ANSI) and is derived from sampling a large

# Box 69-1. Causes of Sensorineural Hearing Loss

#### Newborn

- Anoxia, asphyxia, hypoxia
- Bacterial infections
- Birth trauma
- Congenital syphilis
- Genetic causes, expressed at birth
- Hyperbilirubinemia requiring exchange transfusion
- Prematurity
- TORCH syndrome (toxoplasmosis, other agents, maternal rubella, cytomegalovirus, herpes simplex)

#### Acquired

- Autoimmune inner ear disorders
- Bacterial meningitis
- Congenital or acquired syphilis
- Cranial radiation therapy
- Excessive occupational noise or exposure to loud music
- Genetic
- Glomus tumors
- Head trauma (temporal bone fractures or labyrinthine concussion)
- Herpes zoster
- Human immunodeficiency virus infection/acquired immunodeficiency syndrome
- Labyrinthitis
- Lyme disease
- Measles
- Meniere's disease
- Mumps
- Ototoxic medications
- Vascular disorders

#### Response\*

Modality	Ear		
Modality	Left	Unspecified	Right
Air conduction: earphones			
Unmasked	Χ		0
Masked			Δ
Bone conduction: mastoid			
Unmasked	>	٨	<
Masked	1		l
Bone conduction: forehead			
Unmasked	L	V	L
Masked	Γ		٦
Air conduction: sound field	χ	S	Ø

Figure 69-1 Standardized symbols for recording audiogram results. \*For "no response," use a downward 45-degree arrow pointing to the left for the right ear symbols, and to the right for left ear symbols (e.g., ♀ for no response in the right ear unmasked).

population of ear-disease–free young adults. In other words, if a person's threshold at a given frequency is 20 dB, it means that the individual can hear sound at that frequency only when it is 20 dB louder than that needed by an average disease-free young adult.

**NOTE:** From 1 to 6 of 1000 newborns have severe hearing loss, usually sensorineural in origin. The Joint Committee on Infant Hearing and the National Institutes of Health Consensus Statement recommend screening all infants for hearing loss at no later than 1 month of age. If the screening test result in the very young is abnormal, they should have comprehensive audiologic evaluation at no later than 3 months of age (e.g., behavioral observation audiometry, auditory brain stem response, otoacoustic emissions testing, visual reinforcement audiometry, conditioned play audiometry). Such an evaluation is beyond the scope of this text.

#### **INDICATIONS**

- General screening in children at the earliest age possible
- Exposure to one (or more) of the causes for sensorineural hearing loss (see Box 69-1)
- Speech delay in children
- Persistent behavioral problems or changes in children or the elderly
- Screening of the elderly, especially when performing geriatric assessment (see Chapter 232, Special Considerations in Geriatric Patients)
- Patient complaints of hearing loss
- Persistent serous otitis media, especially bilateral in children
- Anyone undergoing tympanometry with suspected sensorineural hearing loss (an abnormal tympanogram usually implies conductive hearing loss; however, sensorineural hearing loss may also be present)
- Formal audiometric evaluation of a failed screening test

**NOTE:** Up to 5% of school-age children will have fluctuating hearing loss during the school year because of middle ear effusions. Retesting is imperative.

- Patient complaints of tinnitus, dizziness, or vertigo
- After severe head trauma
- After use of ototoxic drugs
- After meningitis, encephalitis, or other serious viral or bacterial infections that could affect hearing
- Occupational screening and follow-up for individuals with noisy work environments

#### **CONTRAINDICATIONS**

- Inexperienced technician
- Acute otitis media
- Local pinna infection that would cause pain from the earphone or earpiece application
- Uncooperative patient
- Uncontrollable background noise in the room when testing
- Occlusion of the canal by cerumen (see Chapter 72, Cerumen Impaction Removal) or a foreign body (see Chapter 76, Removal of Foreign Bodies from the Ear and Nose)

#### **EQUIPMENT**

- Audiometer: These range from simple hand-held screening instruments that test one ear at a time with a limited range of frequencies and intensities to more comprehensive devices. Audiometers may test air conduction alone or may be equipped to test both bone and air conduction. The most comprehensive units test frequencies from 125 to 8000 Hz at 0 to 100 dB. Audiometers are either stationary or portable, and many modern units interface directly with a laptop computer to record, store, and interpret patient evaluations.
- An individual trained in proper techniques for obtaining reliable, reproducible, and valid test results. (For occupational/industrial screening, the individual should be certified by the Council for Accreditation of Occupational Hearing Conservationists [www.caohc.org].)
- Quiet or sound-treated room, preferably tested (by an outside company) for acceptable background/ambient noise levels. If ambient noise levels are too high, thresholds may be artificially elevated, particularly in the lower frequencies.

#### PREPROCEDURE PATIENT PREPARATION

The indications for the procedure should be explained to patients, and they should be reassured that the process is painless. Patients should know that they will be hearing tones of varying degrees of loudness and pitch, and that they should signal both when they first hear a tone and when the tone disappears. They should know how they are expected to demonstrate or signal when they hear the tone (e.g., raising their hand, pushing a button). Patients should sit in a relaxed and comfortable position and look straight ahead. If they can hear noise from outside the earphones or earpiece, they should inform the clinician. If bone conduction testing will be performed, the source and nature of the vibrations should be explained to the patient.

#### **TECHNIQUE**

- The examination must be administered using a properly calibrated instrument in a room with an acceptable level of background noise. The ear canal should have been checked for patency by the clinician.
- 2. The patient should be comfortably seated facing neither the monitor nor the examiner. (Usually patients are seated in a position that provides a side profile view to the examiner.)
- 3. Anything that may interfere with earphone application (or earplug insertion) should be removed (earrings, glasses, hats), and the headphones must be appropriately seated on the patient's head (or the earplugs properly inserted), sealing the ears from environmental noise.
- 4. Instruct the patient to respond to the faintest detectable sound at each frequency. Responses can consist of raising a hand or finger or pressing a test button when sound is first heard. The patient should continue to signal for the duration of audible sound. Having the patient indicate the entire duration of audible sound allows the examiner to determine if the responses

are reproducible. If reproducible, the threshold should be the same at the beginning and at the end for a particular frequency, at least 50% of the time; this can then be recorded. Patients should be tested from low to high decibels and then back to low. This step helps the examiner exclude false-positive responses.

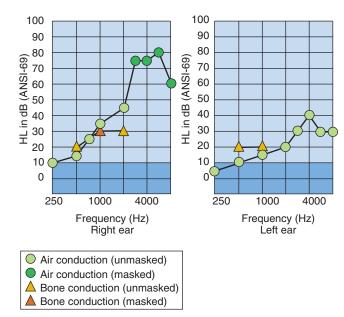

- 5. Threshold testing is initiated in the better ear (or the right ear if hearing is equal in both) with the following recommended sequence of frequencies: 1000, 2000, 4000, 8000, 1000 (repeated), 500, and 250 Hz. Start with 0 dB hearing levels and produce the tones for 1 to 2 seconds unless the patient responds.
- 6. Increase the tone by 5 dB, and, if the patient responds, reduce it by 10-dB increments until it is inaudible.
- 7. Continue repeated ascents in 5-dB increments and descents in 10-dB increments until a 50% reproducible response is obtained. Generally this requires three to four repetitions, with the patient attaining the same response at least half of the time. This result is then entered with the appropriate symbol on the audiogram.
- Test through the frequencies sequentially as previously noted, starting 15 to 20 dB below the threshold of the previously tested frequency. Continue testing until all frequencies have been tested.
- If bone conduction testing is planned, this same sequence can be applied and the results recorded with the appropriate symbols.
- 10. It may be necessary to mask or obscure one sound with another when the difference in hearing loss between the ears is great (e.g., a 40-dB difference for air conduction testing, a 5-dB difference for bone conduction hearing) or there is a 10-dB air—bone gap in the ear being tested. In these situations, crossover of sound to the better ear may occur and artificially lower the threshold of the impaired ear, so masking is applied to the nontest ear. Audiometers are calibrated so that a 10-dB masking noise will block a 10-dB pure signal.

#### INTERPRETATION

Air conduction testing alone can approximate the degree of hearing loss. However, to differentiate between conductive, sensorineural, and mixed hearing loss, it is often best to test both air and bone conduction hearing.

A threshold of up to 20 dB is considered normal. Above that, hearing loss can be divided into degrees of severity (Table 69-1). Certain patterns of hearing loss, especially unilateral, can indicate specific diseases. Hearing asymmetry of more than 20 dB, especially if it is suspected to be sensorineural in origin, may indicate a retro-cochlear lesion or mass (Fig. 69-2). Such patients should be evaluated further with imaging or referred. The tympanometer may be used as an additional tool to assess mobility of the tympanic membrane when conductive hearing loss is diagnosed by audiometry. Conversely, audiometry is often used as an adjunct to tympanometry

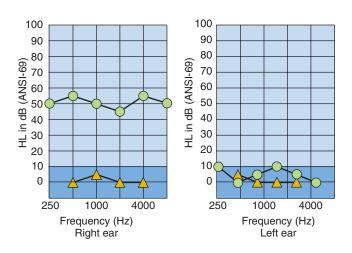

TABLE 69-1 Classification of Severity of Hearing Loss			
Degree of Hearing Loss (dB)	Level of Severity		
0–20	Normal		
21-40	Mild		
41–55	Moderate		
56–70	Moderately severe		
71–90	Severe		
>90	Profound		

**Figure 69-2** Sixty-year-old man with suspected right acoustic neuroma. Note the unilateral hearing loss. (The corresponding tympanograms would be type A or normal.) (Redrawn from Jacobsen JT, Northern JL [eds]: Diagnostic Audiology. Austin, Tex, Pro-Ed, 1991.)

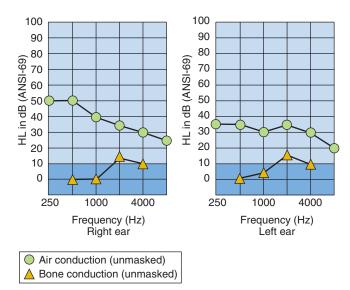

when a persistently abnormal tympanogram is present (see Chapter 75, Tympanometry, for more details).

Figures 69-2 through 69-11 illustrate classic patterns of hearing loss. In the examples, hearing thresholds have been converted to hearing loss (HL). In addition, because each ear was recorded separately, the standardized symbols were not necessary to distinguish left from right.

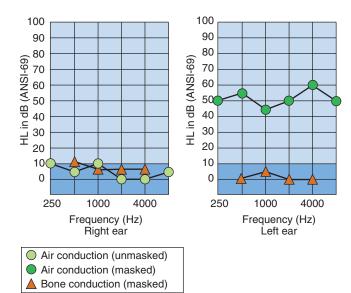

**Figure 69-3** Nine-year-old boy with right acute otitis media with effusion. Using masking, the curves would probably appear the same; however, there would be slightly more assurance of the accuracy of the study. (The corresponding tympanogram would be type B.) (Redrawn from Jacobsen JT, Northern JL [eds]: Diagnostic Audiology. Austin, Tex, Pro-Ed, 1991.)

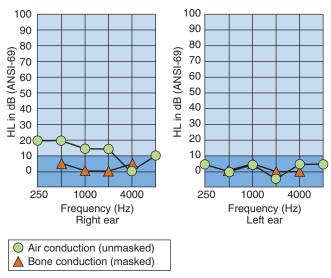

Air conduction (unmasked)Bone conduction (unmasked)

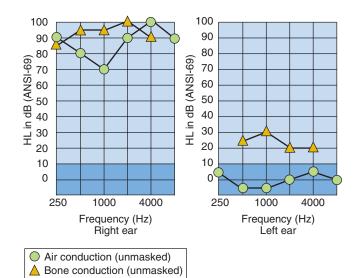

**Figure 69-4** Forty-year-old woman with bilateral otosclerosis. (The corresponding tympanograms would be type A or A<sub>s</sub>.) This disorder is autosomal dominantly inherited with about 40% penetrance. (Redrawn from Jacobsen JT, Northern JL [eds]: Diagnostic Audiology. Austin, Tex, Pro-Ed, 1991.)

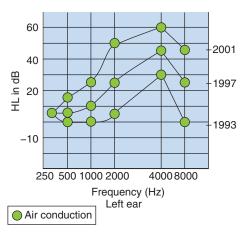

**Figure 69-5** Twenty-year-old man with ossicular disruption on the left after mild head trauma. (The corresponding left ear tympanogram would be type A<sub>D</sub>.) (Redrawn from Jacobsen JT, Northern JL [eds]: Diagnostic Audiology. Austin, Tex, Pro-Ed, 1991.)

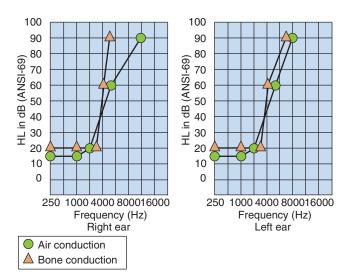

**Figure 69-6** Fifteen-year-old girl with right tympanic membrane perforation. (The corresponding right ear tympanogram would be type B.) (Redrawn from Jacobsen JT, Northern JL [eds]: Diagnostic Audiology. Austin, Tex, Pro-Ed, 1991.)

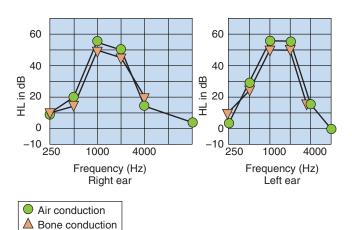

**Figure 69-7** Forty-year-old man with suspected functional (factitious) hearing loss after industrial accident with a single exposure to high-intensity noise (e.g., an explosion). Bone conduction should be intact after a single exposure. (The corresponding tympanograms would be type A or normal.) (Redrawn from Jacobsen JT, Northern JL [eds]: Diagnostic Audiology. Austin, Tex, Pro-Ed, 1991.)

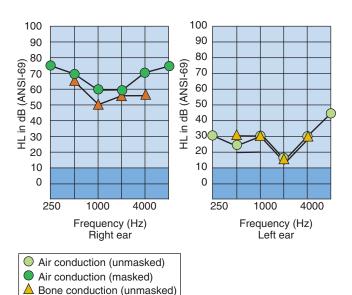

**Figure 69-8** Fifty-five-year-old man with gradually progressive left neurosensory hearing loss over several years. Such a hearing loss can be seen in a person who hunts and shoots left-handed. In most such cases, the audiogram differs from that of presbycusis because it spares the upper frequencies (8000 Hz). (The corresponding tympanogram would be type A or normal.) (Redrawn from Jacobsen JT, Northern JL [eds]: Diagnostic Audiology. Austin, Tex, Pro-Ed, 1991.)

**Figure 69-9** Eighty-year-old man with presbycusis, or hearing loss caused by advancing age. It is usually bilateral, and in men it often affects the higher frequencies more severely. In women, in addition to symmetric high-frequency loss, there may be hearing loss in the lower frequencies. (The corresponding tympanograms would be type A or normal.) (Redrawn from Jacobsen JT, Northern JL [eds]: Diagnostic Audiology. Austin, Tex, Pro-Ed, 1991.)

**Figure 69-10** Fifty-year-old woman with long-term exposure to loud occupational noise, which could include loud music. Note the speech frequencies are more affected than the higher frequencies. (The corresponding tympanogram would be type A or normal.) (Redrawn from Jacobsen JT, Northern JL [eds]: Diagnostic Audiology. Austin, Tex, Pro-Ed, 1991.)

**Figure 69-11** Fifty-two-year-old man with Meniere's disease, predominantly affecting right ear. This hearing loss is often associated with episodes of tinnitus and vertigo, frequently at the same time. Remission can occur, as well as exacerbation. Over time, the hearing loss typically progresses to moderate or moderately severe and persistent. (The corresponding tympanograms would be type A or normal.) (Redrawn from Jacobsen JT, Northern JL [eds]: Diagnostic Audiology. Austin, Tex, Pro-Ed, 1991.)

Bone conduction (masked)

# **AURICULAR HEMATOMA EVACUATION**

George D. Harris

The external ear is subject to a wide variety of injuries. Traumatic injury to the ear is commonly seen in athletes, particularly wrestlers, boxers, and rugby players. Such trauma can also be the result of motor vehicle accidents, assaults, fights, and falls. Although a cushion of subcutaneous fat on the medial surface of the auricle can dissipate a direct force, allowing the skin to slide over the underlying cartilage, the lateral surface lacks this layer of fat. Consequently, blunt trauma over the lateral surface causes shearing forces between the perichondrium and the underlying cartilage, resulting in torn blood vessels in the perichondrium and the formation of a hematoma. The location of the hematoma has classically been described as between the perichondrium and cartilage; however, the hematoma can arise within the cartilage itself.

Untreated lesions affecting the external ear (pinna) can lead to overt disfigurement (cauliflower or wrestler's ear), especially if there is a delay in diagnosis and management.

With trauma, swelling can occur immediately or up to several hours later. Auricular hematomas can also occur spontaneously in older patients and in patients with a blood dyscrasia. A hematoma between the auricular cartilage and the perichondrium deprives the cartilage of its nutrient supply. If left untreated, a hematoma is at risk for secondary infection, perichondritis, cartilage necrosis, contracture, and neocartilage formation. The goals of treatment are to evacuate the hematoma, provide compression in the area, prevent the reaccumulation of fluid, and maintain the cartilage contour. Early treatment helps prevent aseptic necrosis and the loss of cartilage, and, it is hoped, avoids the permanent cosmetic ear deformity (cauliflower ear) from clot organization with fibrin deposition.

This chapter gives primary care clinicians, especially those involved in sports medicine, the information necessary to become familiar with the clinical presentation, appropriate treatment, and complications encountered when faced with an auricular hematoma.

**NOTE:** Patients presenting 7 to 10 days after the time of injury need extensive management. By this time, there is newly formed cartilage and perichondrium; treatment of these patients is beyond the scope of this chapter.

#### **INDICATIONS**

Auricular hematoma: red, reddish-purple, or bluish fluctuant swelling, usually involving the entire lateral auricle. It is also usually quite tender.

#### **CONTRAINDICATIONS**

- Hematoma accompanied by auricular laceration
- Injury beyond the abilities of the clinician

#### **EQUIPMENT**

- Topical antiseptic, such as povidone–iodine (Betadine)
- For aspiration, 18- or 20-gauge needle and syringe

- Adhesive plastic ear drape or fenestrated drape
- Sterile gloves
- No. 15 scalpel blade and holder
- Curved hemostat
- Forceps
- For anesthesia, 30-gauge needle and syringe
- Local anesthetic such as lidocaine 1% (optional, mixed with 1:100,000 epinephrine)
- Small suction catheter or curette
- Penrose drain or sterile rubber band and scissors
- Gauze dressing
- Petrolatum gauze, or cotton balls soaked with petroleum jelly or mineral oil
- For alternative compression techniques: (1) cotton dental roll or tightly folded gauze, and monofilament nylon suture (3-0 or 4-0) with needle and a needle holder; or (2) otolaryngologist's (ear, nose and throat [ENT]) silicone putty or dental impression material (Exaflex type O putty [GC America, Inc., Alsip, Ill])
- Topical antibiotic ointment (bacitracin/polymyxin or mupirocin)
- Eye protection

#### PREPROCEDURE PATIENT PREPARATION

Explain the indications for, alternatives to, and possible complications of the procedure as well as the possible complications from not performing the procedure to the patient. Obtain informed consent, if possible. Also explain the discomfort of injected local anesthetic, and the necessity for the patient to remain very still during the procedure. The patient should be prepared for some mild discomfort during hematoma removal, even with use of the local anesthetic.

#### **TECHNIQUE**

Treatment requires the complete drainage of the hematoma to prevent deformity. This can be done in multiple ways, but the predominant methods are needle aspiration and incision and evacuation. Both should be followed by some type of compression dressing to prevent reaccumulation. There is controversy about which method of drainage is superior. In addition, there are no randomized trials, case-controlled trials, or cohort studies to support one treatment over another regarding the best cosmetic result with the least permanent deformity. Because of the difficulty in removing the entire hematoma, the difficulty in eliminating the dead space, the consequent high risk of recurrence, and the frequent need for a second procedure after needle aspiration, many experts prefer the incision and evacuation technique.

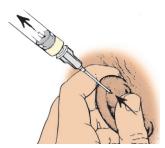

- Position the patient comfortably in the supine position with the injured ear accessible. Universal blood and body fluid precautions should be followed.
- Cleanse the helix with antiseptic solution. Examine for associated lacerations. Anesthesia is achieved by performing a regional block (see Chapter 8, Peripheral Nerve Blocks and Field Blocks)

or by placing a skin wheal of local anesthetic over the hematoma. Many clinicians prefer a regional block because it is very difficult to inject local anesthetic at the site (there is no subcutaneous layer of fat below the skin; consequently, the skin is tightly adherent to perichondrium). The hematoma should not be injected because the anesthetic will only cause the hematoma to expand and increase the damage.

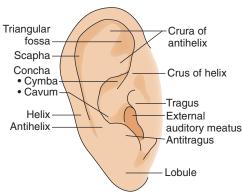

3. Attempt aspiration of the most fluctuant area of the hematoma using an 18- or 20-gauge needle (Fig. 70-1). To ensure complete evacuation of the hematoma, it may be helpful to express the hematoma between the thumb and index finger of the opposite hand while aspirating. This technique may be all that is necessary to evacuate the hematoma, especially if the injury is quite recent and the hematoma is small. If so, proceed to step 9 and then to the "Alternative Compression Techniques" section.

**NOTE:** Using a simple aspiration technique is not adequate for preventing recurrence; consequently one must also use a compression technique. If the hematoma has been present for 6 to 8 hours, it is likely an organized clot. This will be difficult to aspirate, and incision and drainage will probably be required. However, if the patient presents 1 week postinjury, the clot usually has broken down and aspiration once again can be attempted. Larger hematomas may require an open approach or the placement of a drain.

- 4. If aspiration does not completely evacuate the hematoma, incision and evacuation will need to be performed. While maintaining a sterile field, a regional block should be performed. (A regional block is necessary for reasons previously mentioned, including the lack of a subcutaneous layer of fat.)
- 5. While waiting 10 to 15 minutes for the anesthetic to take effect, drape the patient in a manner that keeps his or her hair away from the involved area.
- 6. Note the anatomy of the external ear (Fig. 70-2). With the no. 15 scalpel, make a curvilinear incision over the hematoma, usually 4 to 5 mm in length (and no longer than 1 cm). For the best cosmetic result, the incision should follow the natural recessions of the ear between the helix and antihelix, or the antihelix and the concha (Fig. 70-3). Multiple incisions may be needed. The hematoma may then be expressed or removed using the forceps, gentle suctioning, or curettage.
- 7. Probe the cavity with the hemostat to ensure complete evacuation. Additional manipulation can be performed, if necessary, with digital pressure applied to assist with complete evacuation. Apply pressure until hemostasis is obtained.
- 8. Insert a piece of the Penrose drain or rubber band into the incision. (This should be removed within 48 hours to minimize the risk of infection.)
- 9. Apply antibiotic ointment to the area of the aspiration or incision.

**Figure 70-1** While stabilizing the pinna with the thumb and fingers, puncture the most fluctuant part of the hematoma. Use the thumb and index finger to "milk" the hematoma into the syringe.

**Figure 70-2** Anatomy of the external ear. (From Bisaccia E, Lugo A, Johnson B, Scarborough D: The surgical correction of protuberant ears. Skin Therapy Lett 10:7–9, 2005.)

- 10. Place a piece of sterile dry cotton in the external auditory canal. Then, fit petroleum jelly—treated gauze or petroleum jelly— or mineral oil—soaked cotton balls externally onto the contours of the ear. They should be placed in layers until level with the lateral helical rim. Trimmed gauze squares should then be placed between the ear and the head. Finally, over these layers of gauze or cotton, apply an elastic gauze compression dressing to the ear (Fig. 70-4).
- 11. Prescribe prophylactic oral antibiotics and appropriate analgesia. Antibiotics are important if the hematoma has been present for more than 24 hours, if the hematoma recurs and requires repeated incision and drainage, or if there are signs of cellulitis. They should cover *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and a variety of other gram-negative bacteria.
- 12. Instruct the patient to remove the elastic gauze bandage daily to evaluate the auricle. He or she should return in 48 hours for complete dressing removal and reevaluation. Redrain the ear or reapply the dressing as needed to maintain ear compression for 1 week.

#### **ALTERNATIVE COMPRESSION TECHNIQUES**

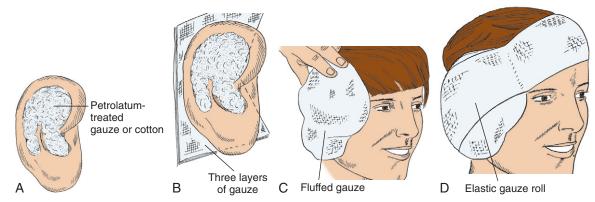

#### **Cotton Dental Rolls**

The alternative compression technique uses cotton dental rolls for compression *after* evacuation. First, follow steps 1 through 7, as described previously.

8. Next, cut a dental roll to fit over most of the hematoma. The smaller remnant of the cut roll will be stitched medially. (Two

Figure 70-3 A curvilinear incision is made.

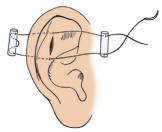

**Figure 70-4** External gauze compression dressing. **A,** Dry cotton is first placed into the ear canal. A conforming material is then carefully molded into all the convolutions of the auricle. **B,** When the convolutions are fully packed, a medial gauze pack is placed behind the ear. A V-shaped section has been cut from the gauze to allow it to easily fit behind the ear. **C,** Multiple layers of fluffed gauze are placed over the packed ear. **D,** The entire dressing is held in place with Kling or an elastic gauze roll. The ear is thus compressed between two layers of gauze, and the packing ensures even distribution of pressure to all parts of the auricle.

- tightly packed pieces of gauze can be stitched in a similar manner, with similar effects.)
- 9. After slightly straightening the suture needle, pass it through one end of the cut dental roll.
- 10. Pass the needle through the most cephalic end of the hematoma from lateral to medial. To use the smaller remaining piece of dental roll as medial compression, pass the needle back and forth through the smaller roll (Fig. 70-5).
- 11. Next, pass the needle through the inferior portion of the hematoma from medial to lateral and then through the other end of the lateral dental roll. If necessary, multiple rolls can be used (Fig. 70-6).
- 12. Tie the suture securely. This creates both lateral and medial compression of the hematoma.
- 13. Apply antibacterial ointment liberally over the dental rolls and the ear. Next, apply an elastic gauze dressing. Oral antibiotics are given as in preceding step 11.
- 14. Ask the patient to return in 24 hours, at which time the elastic gauze dressing is removed. Instruct the patient to continue applying antibacterial ointment until the dental roll dressing is removed in 2 weeks.

**NOTE:** This technique requires an aseptic procedure, anesthesia, and frequent daily dressings. Patients frequently complain of auricular pain for several days after a stitched compressed dressing is applied. The stitched compressed dressing can sometimes lead to pressure necrosis of the auricle.

# ENT Silicone Putty or Dental Impression Material

The technique using ENT silicone putty or dental impression material first follows steps 1 through 7, described previously.

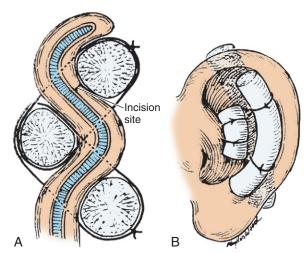

**Figure 70-5** Alternative technique using cotton dental roll for compression.

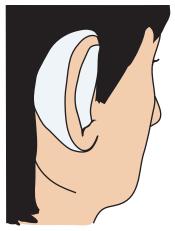

- 8. Next, mold ENT silicone putty to fit the lateral ear just lateral to the external auditory meatus. Wrap the putty medially to match the pinna (Fig. 70-7). The putty contains a hardener, causing it to solidify in a few minutes. Dental impression material can be mixed and used in the same manner (Fig. 70-8).
- 9. An elastic gauze head bandage is then applied for 2 days. It can then be removed. The ENT putty or hardened dental impression material mold should be left in place for a week. Use oral antibiotics as described previously. Instruct the patient to return in 48 hours for reevaluation.

#### POSTPROCEDURE PATIENT EDUCATION

The patient should be aware of the importance of maintaining compression for at least a week. He or she should understand the risk of complications, regardless of management, and should see a clinician if there are signs of infection (e.g., increasing redness, drainage, tenderness, warmth, pain at site). If an external elastic gauze is used to cover the site (see Fig. 70-4), it should be removed daily to check for signs of infection or complications and then reapplied. Oral antibiotics are indicated with any puncture, incision, or laceration of the auricle, so patients should know how to take them

**Figure 70-6** Multiple dental rolls used for compression after evacuation of a large hematoma. **A,** Medial auricular. **B,** Lateral auricular. (From Cummings CW [ed]: Otolaryngology: Head and Neck Surgery, 2nd ed. St. Louis, Mosby, 1993.)

**Figure 70-7** ENT putty used for compression. The putty is molded to fit the ear, and an external compression dressing is used for 2 days. By then the putty is hardened and can be left open to air.

and the importance of taking them. He or she should know when to return to the clinician's office and what possible complications to report.

#### **COMPLICATIONS**

- Bleeding or recurrence of hematoma
- Scar at the site of the incision
- Infection including perichondritis (risk minimized by prophylactic oral antibiotics)
- Auricular deformity, either in spite of appropriate treatment, or because the treatment is inadequate

#### **CPT/BILLING CODES**

69000 Drainage external ear, abscess or hematoma; simple 69005 Complicated

#### **ICD-9-CM DIAGNOSTIC CODE**

380.31 Auricular hematoma

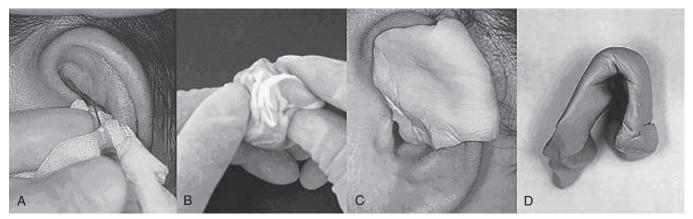

Figure 70-8 Technique for treatment of auricular hematoma using dental impression material. **A,** Follow steps I through 7 of the procedure. **B,** The impression material is prepared using equal parts (one scoop) of base and catalyst of Exaflex type O putty (GC America, Inc., Alsip, III), which is composed of vinyl polysiloxane and spontaneously cures after base and catalyst are mixed. The materials are kneaded in the hands for I minute or until uniform in color. **C,** The mixed impression material is placed on both the lateral and medial surfaces of the auricle. Make sure the lateral surface of the auricle is adequately covered, including the cavum concha area, to maintain the normal contour of the auricle. It takes about 3 to 5 minutes for the Exaflex mixture to cure spontaneously. **D,** The dental impression material is contoured into the shape of an inverted "U," which acts to stabilize the frame. The cured dental frame is fixed and stabilized with paper tape and then dressed simply with gauze. The patient is checked again 3 days after the procedure, and then on day 7. At that time, the impression material is removed. (From Choung YH, Park K, Choung PH, Oh JH: Simple compressive method for treatment of auricular haematoma using dental silicone material. J Laryngol Otol 119:27–31, 2005.)

# EARLOBE REPAIR

Dennis LaRavia

Constant or repetitive traction by jewelry worn in a pierced earlobe may eventually cause a large, elongated hole (Figs. 71-1A and 71-2). Over time, the defect may even extend through the tip of the lobe, creating a bifid lobe that is completely reepithelialized (Fig. 71-1B). More acutely, an earring can be pulled or ripped through the lobe, resulting in a laceration. This area is also a common site for cysts. Regardless of the cause, the results are often unacceptable cosmetically to the patient; it may also become impossible to wear a pierced earring at that site. Although some patients will opt for clip-ons or piercing at an adjacent site and wear large earrings to cover the defect, others will choose to repair the lobe.

Primary care clinicians can repair the earlobe in the office, often bringing great satisfaction to a patient by improving both cosmetic appearance and convenience with jewelry. The usual charge from a plastic surgeon for such a repair is \$450 to \$650; consequently,

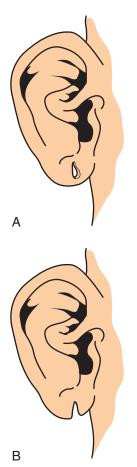

Figure 71-1 The torn earlobe defect. **A,** Incomplete tear with resulting large hole defect. **B,** Complete tear.

primary care clinicians can usually work something out that is beneficial to both the patient and the clinician.

#### **EOUIPMENT**

- Sterile preparation and setup (alcohol or chlorhexidine, sterile drapes and gloves).
- Lidocaine 1% or 2%, without epinephrine.
- Laceration repair kit including skin hooks and 6-0 nylon suture.
- Scalpel with a no. 15 or 15c blade, and possibly a no. 11 blade.
- Antibacterial ointment or petroleum jelly.
- Sterile dressing.
- If available, an electrosurgical or radiofrequency unit (e.g., Ellman Surgitron) with a fine cutting needle or wire works well to excise the tissue (see Chapter 30, Radiofrequency Surgery [Modern Electrosurgery]).

#### PREPROCEDURE PATIENT PREPARATION

In spite of the fact that the patient desires this procedure, it is often considered a cosmetic procedure by insurance companies and may not be a covered expense. Explain this possibility, as well as the possible complications of the procedure, which may include discomfort, bleeding, infection, and a cosmetic defect. The patient should be aware that there will be a scar after repairing an earlobe, and that his or her earlobe will not be identical to the contralateral one. However, every attempt will be made to minimize any additional cosmetic defect. If the patient tends to develop keloids or hypertrophic scars, these may result from the procedure. Obtain informed consent. Also explain the discomfort of injected local anesthetic and the necessity for the patient to remain very still during the procedure.

#### **TECHNIQUE**

- After a sterile preparation is performed, sterile technique is used, and the clinician should observe universal blood and body fluid precautions.
- 2. A wheal of lidocaine without epinephrine placed circumferentially around the entire base of the ear will provide good anesthesia (ear block; see Chapter 8, Peripheral Nerve Blocks and Field Blocks). The concha and ear canal retain sensation. Use of the circumferential block as opposed to injection directly into the lobe avoids distortion of the local anatomy.
- 3. Excise the defect with a no. 15 or 15c blade, a no. 11 pointed blade, or with the electrosurgical or radiofrequency unit (e.g., Ellman Surgitron; level 2, pure cut, Varitip or fine needle; Figs. 71-3 through 71-5). If the defect is a large hole, it is often easier just to excise all the way through the lobe to create a "V" (see Fig. 71-3). Various sterilized objects with a flat surface have been used to support the lobe during the excision because it is so flaccid, but with gentle traction by the nondominant hand, the lobe should remain stable. The radiofrequency unit makes this step easier, especially if the defect is a hole and you are trying to

Figure 71-2 Chronic earlobe laceration.

preserve the lower intact rim of tissue (see Figs. 71-4 and 71-5). Care should be taken to excise a smooth line and to treat the exposed subcutaneous tissue and wound edges extremely gently. If needed, skin hooks should be used. Absolutely avoid grasping the skin edges with forceps; this delivers a crushing-type force, induces unnecessary trauma, and increases scarring. Earlobe cysts are removed and repaired in the same manner (Fig. 71-6).

- 4. Control bleeding with pressure.
- 5. Close the skin edges anteriorly to posteriorly with interrupted 6-0 nylon. It is wise to begin suturing anteriorly first so that any malalignment is confined to the posterior aspect. Also, sutures may be placed intermittently at first, and then the gaps filled in to conclude the repair. Proper approximation at the tip of the lobe is important (Fig. 71-7; see also Figs. 71-3 and 71-4). The wound edges may try to invert, and a vertical mattress stitch may help prevent this.
- 6. Apply antibacterial ointment or petroleum jelly.
- 7. Place a pack behind the earlobe and against the mastoid to secure the lobe and ensure that it will not suffer trauma or excessive motion. Cover the wound with a sterile pressure dressing. Overall, patients generally appreciate the final result (Fig. 71-8).

#### POSTPROCEDURE PATIENT EDUCATION

- 1. For the first few hours, the patient should lie on the side that was repaired to compress the area and reduce bleeding.
- 2. The patient should remove the dressing in 12 to 24 hours, and thereafter wash the area gently twice a day with alcohol or hydrogen peroxide on cotton-tipped applicators. All blood and crusts should be removed to minimize the risk of scarring and infection. A small amount of antibacterial ointment (avoid neomycin, which can inhibit reepithelialization) or petroleum jelly should then be applied with a new cotton-tipped applicator.
- The patient should return for suture removal in 5 days. Some clinicians use Steri-Strips to give additional support for several days.
- 4. Repiercing of the ear may be performed after 6 to 8 weeks in a location off of the wound line.
- The patient should be instructed to avoid heavy, dangling, or large loop earrings in the future to avoid repeated, undue traction on the lobe.

#### **CPT/BILLING CODES**

# CERUMEN IMPACTION REMOVAL

Michael McHenry

Cerumen impaction is one of the most common otologic problems encountered by primary care clinicians (approximately 150,000 ears are irrigated per week in the United States to remove cerumen). Cerumen is a naturally occurring lubricant and protectant of the external auditory canal. The predominant form is a wet, sticky, honey-colored wax that can darken, but a dry, scaly form occurs in some patients. Normally cerumen is carried from inside the canal to the outside by tiny cilia. Accumulation of cerumen can cause decreased hearing, tinnitus, vertigo, infection, or a sensation of increased pressure. The hearing loss is usually quite sudden when the cerumen seals off the canal and is often described by the patient as a "blocked ear." Accumulation is common in elderly patients and in patients working in dusty environments. Patients often do a poor job of removing cerumen with cotton-tipped sticks or over-thecounter preparations, leaving the clinician to complete the procedure. In fact, overzealous use of these applicators frequently disrupts the natural ciliary cleaning process. For removal by the clinician, topical anesthesia may be desired; foreign bodies may also need to be removed (see Chapter 76, Removal of Foreign Bodies from the Ear and Nose, which also describes a technique for injecting anesthetic for external canal field block). The overall goal of this procedure is to remove cerumen under direct visualization or by irrigation without causing injury. The risk of injury is not to be taken lightly because ear irrigation is one of the more common causes of iatrogenic injuries cared for by otolaryngologists. Asymptomatic cerumen buildup does not require removal; rather, the patient should be taught how to perform his or her own ear irrigation to clean the ears.

#### **INDICATIONS**

- Tympanic membrane or ear canal obscured by cerumen with otologic complaint
- Patient complaint of decreased hearing, otalgia, tinnitus, vertigo, or unsteady gait associated with cerumen
- External otitis associated with cerumen (the ear should be dried meticulously after the procedure)
- Clinician needs to examine an ear canal or tympanic membrane obscured by cerumen
- Patient needs hearing tested and ear canal(s) obscured by cerumen

#### **CONTRAINDICATIONS**

- Uncooperative patient or infant who cannot be adequately restrained.
- Clinician unfamiliar with or unable to define anatomy of the external auditory canal.
- Patient with distorted anatomy (e.g., prior or current injury obscuring normal anatomy), although this is a relative contraindication.
- Previous ear surgery with resultant scarring and increased risk of perforation (relative contraindication).
- Known or suspected cholesteatoma.

- The affected ear is the only hearing ear (relative contraindication, but referral should be considered).
- For irrigation, acute otitis media or known/suspected perforation
  of the tympanic membrane is a contraindication. In these situations, the curette or suction catheter should be used under direct
  visualization.

#### **EQUIPMENT**

- Equipment necessary for clinician to observe universal blood and body fluid precautions (gloves, mask, goggles)
- Ear curette
  - Metal: rigid, Buck, Shapleigh, or Yankauer; flexible, Billeau flexible earloop
  - Plastic: Flex-loop ear curette, disposable ear curette, or infant ear scoop
- Otoscope with moveable posterior lens or shield, or ear speculum and light source
- Ear forceps
- Ball-tipped ear hook
- Local anesthetic solution or suspension (e.g., lidocaine solution)
- For suction: Various ear suction catheters with suction source (Fig. 72-1)

NOTE: Hollow ear candles have been found ineffective.

- For irrigation
  - Ear syringe (large stainless steel syringe with irrigant deflector),
     or a commercially available jet irrigator (on "ENT table units,"
     or an oral Waterpik [Water Pik, Inc., Fort Collins, Colo]), or
     a 22-gauge butterfly intravenous catheter tubing (with needle
     and butterfly removed) and a 20- to 50-mL syringe. An 18-gauge
     Angiocath type IV catheter can also be used with a syringe.
  - Lukewarm tap water ("lukewarm" is confirmed when a drop placed on the inner forearm of the examiner is comfortable, similar to testing baby formula).
  - Towels, Chux, or plastic drape.
  - Cotton gauze strip.
  - Emesis or ear basin to collect irrigant.
  - Aqueous-based ceruminolytics, in contrast to the traditional organic or oil-based preparations, have been found to be most effective in in vitro studies. Distilled water can be used, but 3% hydrogen peroxide or 5% to 10% sodium bicarbonate was superior in studies. Olive oil was not useful. Sialic acid took twice as long as distilled water to dissolve cerumen. The sodium bicarbonate solution can be made at home by dissolving ¼ teaspoon sodium bicarbonate (baking soda) in 10 mL of water.

#### PREPROCEDURE PATIENT PREPARATION

- For curette and suction removal, discuss the chance of perforation and minor trauma to the ear canal associated with pain.
- For irrigation removal, discuss the risk of perforation and potential dizziness during the irrigation. Local discomfort may also be experienced, especially when the ear syringe is used.

Figure 72-1 Suction catheters (including Frazier) (A) and basic suction pump (B) can assist in managing ear canal obstruction.

- Stress the importance of remaining still during the procedure.
- The patient should expect to hear occasional loud noises while the clinician is working in the ear, especially if suction is used.
- Patients should be aware that firmly adherent cerumen frequently tears the skin lining the ear canal when removed, regardless of the technique used. As a result, there may be some bleeding. Slight bleeding does not indicate perforation. There is also a slightly increased risk of external otitis after cerumen removal. For both reasons, antibiotic ear drops are frequently prescribed.

#### **TECHNIQUE**

The clinician should follow universal blood and body fluid precautions when performing these procedures.

#### **Curette or Suction Technique**

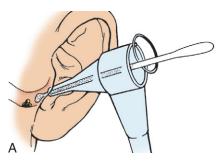

A curette is usually the fastest way to remove cerumen and may be preferred for small amounts of easily visible and reachable wax. It is also usually the easiest method for children, who may find it difficult to remain still for suction or irrigation. In adults, suction can be used for deeper or slightly more adherent impactions. Suction works best for multiple tiny fragments or for soft cerumen; it often fails when there is a single, hard, irregular, and impacted cerumen plug. Young children are often frightened by the noise suction makes. For children and adults, irrigation will be necessary for dense, adherent, or circumferential impactions.

 Seat the patient on the examination table. If available, a neck rest, such as those on a dental or otolaryngology (ears, nose, throat [ENT]) chair, may help adults remain immobile. Children often tolerate the procedure better if held securely or swaddled with a sheet in a parent's lap or, if supine, with the parent or assistant stabilizing the head.

- 2. Using the otoscope, first visualize the opposite canal to become familiar with the patient's anatomy. Next, visualize the cerumen in the affected canal by applying traction on the helix as necessary. In adults, traction is usually applied posteriorly and upward on the pinna while simultaneously pulling it slightly out from the head. In the small child, the pinna is pulled down, back, and slightly out from the head. Five to 10 mL of local anesthetic instilled in the ear will usually result in increased patient comfort for the duration of the procedure; however, it may obscure the canal briefly, so sometimes it is better just to remove the cerumen.
- 3. Using the selected curette, ear hook, or suction catheter, reach through the partially open magnifying posterior lens of the otoscope and gently remove the impacted cerumen. Take care to avoid traumatizing the bony ear canal. Work either through the scope (Fig. 72-2A) or, after identifying the location of the cerumen, by direct visualization (Fig. 72-2B).

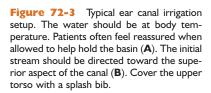

**NOTE:** The clinician's hand should be stabilized by remaining firmly in contact with the patient's head at all times to minimize the risk of scraping the wall of the external canal or perforating the tympanic membrane. Even the most cooperative patient may move involuntarily because of a stimulated vagal nerve cough reflex.

- 4. If hard wax is encountered, installation of 8 to 10 drops of 3% hydrogen peroxide or 5% to 10% sodium bicarbonate for 5 to 10 minutes should facilitate removal. For wax adherent to the tympanic membrane, irrigation or suction may be necessary. Suction catheters (see Fig. 72-1) are quite loud when used in the external canal, so if suction is used, the patient should be warned and instructed not to pull away from the noise.
- Firmly adherent cerumen frequently tears epithelium as it is removed. Consider prescribing topical otic antibiotics if epithelium is disrupted.

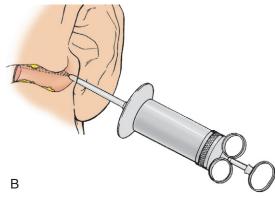

**Figure 72-2 A,** Removal through the otoscope. **B,** Often, foreign bodies or cerumen in the ear canal can be removed with direct visualization after careful, magnified, otoscopic examination is completed. Notice how the patient's head is supported and the clinician's hand rests on the patient's face.

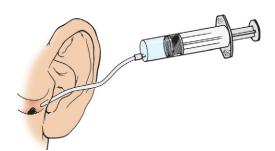

#### **Irrigation Technique**

The irrigation technique (Figs. 72-3 through 72-5) takes longer than the curette or suction technique. However, irrigation rarely fails; it is the safest technique; it is the technique used most often by non-otolaryngologists; and it is often used when other techniques have failed or caused pain.

- 1. Fill the irrigator (syringe) with body-temperature tap water. Using water at this temperature reduces the chance for stimulation of the vestibular reflex, causing nystagmus and nausea. Test the water temperature by placing a drop on the inner forearm of the examiner. It should feel neither warm nor cold to touch.
  - **NOTE:** If the jet irrigator (e.g., Waterpik) is used, adjust the pressure to the *lowest* setting to reduce the risk of perforation or acoustic trauma. Even at low pressures, jet irrigators have been known to rupture the tympanic membrane; therefore, some experts no longer recommend use of jet irrigators for cerumen removal. If a jet irrigator is used, the clinician may want to use a "safe" irrigation tip (see Suppliers section).
- 2. Protect the patient with a towel, Chux, or plastic sheet to collect excess water.
- 3. Have the patient tilt his or her head to the side being irrigated, and hold the ear basin (Fig. 72-6) below the patient's earlobe. Patients often feel reassured when allowed to help and hold the basin. Advise the patient not to pull his or her head away from the irrigating tip.
- 4. Using the selected device, direct the water jet superiorly toward the occiput, allowing space for the return of the water and cerumen. Directed in this manner, water circulates first above and behind the cerumen, and then it pushes the cerumen out of the ear. The irrigation should *not* be directed onto the tympanic membrane. No irrigation device should be inserted more than 1 cm into the canal.
  - If the ear syringe is used, fairly vigorous force may be needed.
     The use of large (25- to 50-mL) syringes prevents excessive

**Figure 72-4** Alternative irrigation setup. Use an 18-gauge plastic intravenous catheter or butterfly tubing with needle and butterfly removed.

- pressure. Be sure that air bubbles are removed from the syringe before use.
- If the jet irrigator or catheter—syringe unit is used, after directing the flow superiorly, rotate the tip back and forth to change the direction of spray.
- 5. Often the cerumen washes out in one or two large pieces in a few seconds, at which point the canal is reexamined. If the canal is clear, stop the irrigation and dry the canal by inserting and removing a small length of cotton gauze. If the patient has otitis externa, the ear canal should be dried meticulously.
- 6. Occasionally the impacted cerumen will need to be prodded with an ear curette. If irrigation is still unsuccessful after a few moments, terminate the procedure and send the patient home to use a liquid ear wax softener. Have the patient return in a few days for a repeat irrigation.
- 7. Consider prescribing topical otic antibiotics if the epithelium was disrupted to provide prophylaxis against external otitis.

#### **COMPLICATIONS**

- Tympanic membrane perforation and damage to ossicles with possible hearing loss
- Otitis externa
- Vertigo or nausea and vomiting
- Minor canal wall abrasions—as mentioned earlier, some bleeding may occur if hard wax is adherent to the epithelium and causes desquamation with removal (if noted, antibiotic otic drops should be used for a few days)
- Tinnitus

**Figure 72-5** Waterpik oral cleaning system (not marketed by the company for cerumen impaction removal). (Courtesy of Water Pik, Inc., Fort Collins, Colo.)

Figure 72-6 Basin cup that fits under ear.

#### POSTPROCEDURE PATIENT EDUCATION

Instruct the patient to contact the clinician's office for fever or vertigo or for decreased hearing, purulent drainage, or pain in the affected ear. Slight bleeding from the affected ear may be expected if the skin was disrupted. Diabetic and other immunocompromised patients should be especially observant for signs of infection because they are prone to development of malignant otitis externa (often due to *Pseudomonas*), with its resultant high morbidity and mortality rates.

Inform patients with recurring cerumen impactions, unless contraindicated, to perform monthly or bimonthly ear cleansing using hydrogen peroxide, 5% to 10% sodium bicarbonate (mixed as previously described in Equipment section), or distilled water as an irrigant from a squeeze bulb ear syringe (similar to nasal bulb syringe used in newborns; both are available at local pharmacies). Advise the patient to avoid self-instrumentation of the ear canal with cotton-tipped applicators or any other instrument. It may be helpful to explain that cotton-tipped applicators or other instruments often disrupt the cilia and other natural ear cleansing mechanisms, even causing an accumulation of cerumen. Cotton-tipped applicators should be used only on the external ear and never inserted into the canal. Another option is the instillation of two to three drops of mineral oil, pure vegetable oil, or liquid docusate sodium every couple of weeks in the ear canal to soften the wax (these are contraindicated with suspected perforation). There is no consistent evidence that one ceruminolytic is better than another. Patients who use hair spray should cover the ears when spraying to avoid hardening the cerumen.

#### **CPT/BILLING CODE**

69210 Removal impacted cerumen (separate procedure), one or both ears

# Tympanocentesis and Myringotomy

Mark S. Grubb

Tympanocentesis is a puncture of the tympanic membrane performed with a hollow needle to aspirate fluid for diagnostic or therapeutic purposes. A myringotomy is an incision in the tympanic membrane made with a myringotomy knife. Ventilation of the middle ear space by either method instantly relieves pain and pressure associated with acute otitis media. Culture of middle ear aspirate establishes disease etiology and enables precisely targeted antibiotic therapy. Tympanocentesis or myringotomy can also relieve hearing loss and discomfort associated with chronic middle ear effusions.

At this time, myringotomy is performed almost exclusively during tympanostomy tube insertion, for which the patient is under general anesthesia. Tympanocentesis is the more suitable procedure for primary care settings. Needle puncture of the tympanic membrane is easy to accomplish, requires only local anesthesia, poses less risk than a myringotomy incision, and permits drainage for up to 5 days.

The ear that would benefit from tympanocentesis will have fluid behind the tympanic membrane, and the membrane will have either a bulging or retracted appearance resulting from positive or negative pressure in the middle ear space. Despite this distorted appearance, the location of the umbo and the orientation of the manubrium usually remain discernible. Tympanocentesis is performed on the inferior half of the membrane at the location of maximal bulge, usually in the anterior quadrant. The puncture or incision should be performed nearer to the tip of the manubrium than to the fibrous annulus. Do not perform the procedure on the fibrous annulus, over the incus or stapes, or directly over the round window (Fig. 73-1).

#### **INDICATIONS**

#### **Tympanocentesis**

- For immediate relief of pain and pressure associated with acute otitis media
- For aspiration of middle ear fluid for culture to select precisely targeted antibiotic therapy
- As an adjunct to watchful waiting for acute otitis media; tympanocentesis relieves symptoms and promotes therapeutic drainage during the observation period, and enables accurate drug selection for patients who remain symptomatic after 48 hours
- For identifying pathogens in persistent acute otitis media or in episodes that have failed to respond to antibiotic therapy
- For otitis media diagnosed in immunocompromised patients or those with multiple antibiotic allergies
- For complicated otitis media such as that associated with unusually severe pain, signs of toxicity, facial nerve palsy, mastoiditis, meningitis, encephalitis, brain abscess, or dural sinus thrombosis

- For alleviation of conductive hearing loss or discomfort associated with chronic serous otitis media
- As an alternative therapy for patients who wish to avoid antibiotics

#### **Myringotomy**

- For immediate relief of pain and pressure associated with acute otitis media
- · For placement of tympanostomy tubes

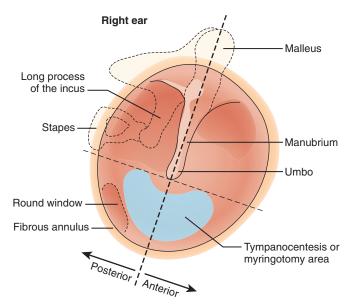

#### **CONTRAINDICATIONS**

- Known anomalous positioning of the jugular bulb
- Cochlear implant
- Acute otitis externa (relative contraindication)
- Uncooperative patient (relative contraindication)
- Obscure landmarks (consider referral to otolaryngologist)

#### **EQUIPMENT**

- Local anesthesia: 0.5 mL of 8% tetracaine otic solution, eyedropper, cotton balls, 3% hydrogen peroxide, tissue wicks
- Tympanocentesis
  - CDT (channel directed tympanocentesis) speculum method: A CDT (Walls Precision Instruments, Baker City, Ore) 3- or 5-mm Speculum and Aspirator bulb, and a Welch-Allyn otoscope with pneumatic, diagnostic, or operating head. The CDT instrument has a protected needle and other safety features enabling safe completion of the procedure without restraints for most patients (Fig. 73-2).
  - Tympanocentesis collector method: A 3-inch 20- or 21-gauge spinal needle, a Medtronic Xomed Tympanocentesis Collector (Medtronic ENT, Jacksonville, Fla), an otoscope with operating head, a papoose board or other patient restraint (as needed), and a vacuum pump or wall suction (Fig. 73-3).
  - Syringe method: A 3-inch 20- or 21-gauge spinal needle bent at the hub to about 60 degrees, a 3-mL syringe, an otoscope with operating head, and a papoose board or other patient restraint (as needed; Fig. 73-4).
- Myringotomy
  - Myringotomy knife, an otoscope with operating head, and a papoose board or other patient restraint (as needed; Fig. 73-5).
  - Aspiration after myringotomy will require a vacuum pump, and either a Juhn Tym-Tap aspirator (Medtronic) or a Baron suction tube combined with an inline suction trap.

NOTE: In all instances where an operating otoscope head is used, the clinician may elect to move the lens of the otoscope out of the

**Figure 73-1** Tympanic membrane of the right ear. (Courtesy of David Spaugh.)

Figure 73-2 Tympanocentesis with CDT Speculum and CDT Aspirator bulb.

**Figure 73-3** Tympanocentesis with Xomed Tympanocentesis Collector attached to vacuum pump.

**Figure 73-4** Tympanocentesis with spinal needle attached to 3-mL syringe.

field of view and use a head-mounted portable binocular microscope instead.

# PREPROCEDURE PATIENT EDUCATION AND FORMS

Explain the indications, the procedure, risks of the procedure, options for procedural anesthesia, and available alternative therapies. The patient should be warned that working near the tympanic membrane can be noisy. Unless conscious sedation is used, they should also be aware that they will experience some discomfort. Obtain signed informed consent and document it in the patient's chart. A sample patient education form is available online at www. expertconsult.com.

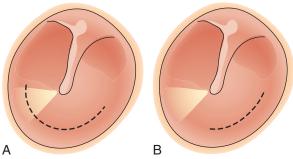

#### **TECHNIQUE**

#### **Tympanocentesis**

- 1. Remove any cerumen from the canal (see Chapter 72, Cerumen Impaction Removal).
- 2. Initiate the desired preprocedure anesthesia or analgesia. The methods most frequently used are the following:
  - 8% tetracaine otic solution applied topically to the membrane, held in place for 15 minutes with a cotton dam or wick
  - Acetaminophen with codeine, given orally 30 minutes before the procedure
  - Midazolam (requires training in conscious sedation; see Chapter 2, Procedural Sedation and Analgesia) or pediatric sedation (see Chapter 7, Pediatric Sedation and Analgesia)

Figure 73-5 Myringotomy with Xomed disposable myringotomy knife.

**Figure 73-6** Locations for myringotomy. A tympanocentesis could precede either of these myringotomy incisions in the same location. **A,** Wide myringotomy incision through the tympanic membrane might be used in patient with refractory purulent otitis media or for prolonged drainage of pus if necessary. **B,** More limited myringotomy incision.

**NOTE:** Topical anesthetic solutions are typically bacteriostatic. If the clinician intends to culture aspirated fluid, excess anesthetic solution must be removed from the external auditory canal before the procedure.

- 3. Lay the patient in the supine position with head turned to one side. A papoose restraint is usually necessary when the procedure is performed with an unprotected sharp. Use a tissue wick to remove excess anesthetic solution from the canal and membrane.
- 4. Insert the speculum into the ear canal, and visually determine the point of the intended perforation.
- 5. Extend the needle 2 mm through the tympanic membrane at the point of maximal bulge in the inferior portion.
- Aspirate fluid while the tip of the needle is in the middle ear space, as follows:
  - CDT method: Release thumb pressure on the aspirator bulb (see Fig. 73-2).
  - Collector method: Occlude the trap opening with a finger (see Fig. 73-3). An assistant can be helpful with this step.
  - Syringe method: Retract the syringe plunger with the thumb (see Fig. 73-4).
- 7. Retract the needle and then the speculum from the patient's ear.
- 8. Irrigate the canal with 3% hydrogen peroxide solution and remove excess fluid with a tissue wick.

#### **Myringotomy**

- 1. The steps for office myringotomy are essentially the same as for tympanocentesis, except a myringotomy knife is used to make a curved incision in the tympanic membrane (see Fig. 73-5). A myringotomy may be preceded by tympanocentesis in the same location (Fig. 73-6).
- 2. If aspiration is to accompany myringotomy, it is accomplished by reentering the myringotomy incision with aspiration equipment before removing the speculum from the patient's ear. (If fluid is sent for culture, this would be the method to obtain it. Postprocedure aspiration of exudate directly from the canal is not recommended for culture because the aspirate may be contaminated by canal flora.)
- Do not irrigate the ear canal or use peroxide-saturated wicks after myringotomy.
- 4. Other than applying topical antibiotic solutions, the ear canal should be kept dry for 5 days after myringotomy.

#### **COMPLICATIONS**

Potential complications include chronic perforation, puncture of abnormally positioned bulb of jugular vein, a scar on the tympanic membrane, and hearing loss (if using a method with unrestricted needle traverse). Authors of the current medical literature and those who use tympanocentesis in clinical settings describe a zero incidence for these complications. Otitis externa is also a potential, less threatening complication.

#### POSTPROCEDURE MANAGEMENT

#### **Tympanocentesis**

Purulent drainage may continue for up to 5 days. Twice-daily cleaning of the external canal with peroxide and tissue wicks will remove residual drainage and prevent external otitis.

#### **Myringotomy**

Purulent drainage may continue for up to 5 days. Peroxide rinse of the external canal is not recommended after myringotomy. Patients should be instructed to keep the ear dry for 5 days after myringotomy, with particular attention to care when bathing or washing hair. A cotton ear plug coated with a thin film of petroleum jelly works well during these times.

A sample postprocedure patient education form is available online at www.expertconsult.com.

#### **CPT/BILLING CODES**

**NOTE:** Presently, there is no differentiating CPT code for tympanocentesis. The procedure is coded and billed using the myringotomy code set.

69420 Myringotomy including aspiration and/or eustachian tube inflation (also used for tympanocentesis)

69420.LT or 69420.RT (Use LT or RT modifiers for the left or right ear)

69420.50 (Use the .50 modifier for bilateral procedures)

69421 Myringotomy including aspiration and/or eustachian tube inflation requiring general anesthesia

#### **ICD-9-CM DIAGNOSTIC CODES**

- 381.00 Otitis media, NOS, with effusion
- 381.01 Otitis media, acute serous
- 381.4 Otis media, nonsuppurative (allergic, exudative, transudative, secretory, mucoid)
- 381.4 Otis media, nonsuppurative with effusion
- 381.10 Otitis media, chronic serous, simple
- 382.00 Acute suppurative otitis media without spontaneous rupture of eardrum
- 382.01 Acute suppurative otitis media with spontaneous rupture of eardrum
- 382.3 Otitis media, chronic suppurative
- 388.70 Otalgia
- 993.0 Otitis media due to barotrauma
- 909.4 Otitis media due to barotrauma, late effect

# REDUCTION OF DISLOCATED TEMPOROMANDIBULAR JOINT (WITH TMJ SYNDROME EXERCISES)

Robert S. Tan • Grant C. Fowler

Although anyone may dislocate his or her temporomandibular joint (TMJ), such a dislocation occurs more commonly in older patients. Although the cause is often uncertain, TMJ dislocation can be associated with rheumatoid arthritis or osteoarthritis. Excessive laughter or yawning may also cause a luxation of the TMJ. Trauma can cause a TMJ dislocation; the history often reveals a blow to the chin while the mouth is slightly open. Dystonic reactions to medications can also cause dislocation. Patients who have had one dislocation are prone to further dislocations. Anterior dislocation occurs when the muscles and ligaments supporting the mandible are relaxed enough to allow the condule to jump anteriorly over the articular eminence of the fossa. (Although posterior dislocation can occur, it is rare and usually the result of a direct blow to the chin that does not break the condylar neck.) Once the dislocation occurs, trismus and muscle spasms prevent the joint from returning to its natural position. Consequently, the patient presents to the clinician with an open mouth that cannot be closed and difficulty swallowing and talking. For anterior dislocation, pain is localized anterior to the tragus, and there will be a visible and palpable preauricular depression from the displacement of the mandibular condyle. Although unilateral dislocation causes a deviation away from the affected side, the more common bilateral dislocation prevents the mouth from being closed.

For clicking or tender TMJs, splinting by a dentist or oral surgeon is a common treatment. In the "Postprocedure Patient Education" section, three published alternatives to splint therapy are described, and a TMJ "rest" program is elucidated. For an acutely painful TMJ, as described in the "Passive Reduction" section, the joint can also be injected with a lidocaine/corticosteroid mixture.

#### **INDICATIONS**

Unilateral or bilateral TMJ dislocation(s) without fractures (the dislocation should be confirmed with a radiograph, which also rules out a fracture)

#### **CONTRAINDICATIONS**

Fractured condyle(s) (patient should be referred to a maxillofacial surgeon)

#### **EQUIPMENT**

- Gloves, mask, goggles
- Gauze to protect the clinician's thumbs
- Parenteral muscle relaxant may be helpful (e.g., diazepam, lorazepam, midazolam)

- Examination chair with firm neck rest
- (Optional) 5 mL of 2% lidocaine (Xylocaine) in a 10-mL syringe with a 25-gauge needle, 4 × 4 inch gauze sponges, povidone iodine (Betadine) solution
- (Optional) Injectable corticosteroid

#### PREPROCEDURE PATIENT PREPARATION

Inform the patient which technique(s) will be attempted, whether passive or active, and the indications for, risks of, and alternatives to these techniques. If the passive technique is to be attempted, explain how muscle spasm is inhibiting reduction of the dislocated TMJ, and that an intravenous muscle relaxant may be all that is necessary.

**NOTE:** If an intravenous muscle relaxant is used, the patient should be accompanied by someone and not be allowed to drive that day. The patient should also be aware that his or her urine would test positive for benzodiazepines should drug testing be done.

Alternatively, an injection of local anesthetic into the TMJ may allow patients to reduce the dislocation themselves. If the active technique is necessary, patients should know that while the joint is being reduced, they may experience considerable pressure on the molars. They may also experience some referred pain to the neck, face, or ear, as well as mild, aching TMJ arthralgia after the reduction. Stress the importance of trying to remain relaxed and immobile while the joint is being reduced.

#### **TECHNIQUE**

#### **Passive Reduction**

One theory suggests that muscle spasm is all that is inhibiting reduction; therefore, an intravenous muscle relaxant should suffice. However, another theory suggests that painful stimuli arising from the capsule cause the muscle spasm to maintain the dislocation. Consequently, injection of lidocaine into the joint would be needed to overcome these painful stimuli and allow for passive reduction. The choice of technique may be determined by patient desire or by what is available in the clinic setting. Universal blood and body fluid precautions should be followed when performing this procedure.

1. If *intravenous muscle relaxation* is chosen, administer titrating doses of a muscle relaxant (e.g., diazepam, lorazepam, midazolam).

Figure 74-I Injection of lidocaine into the joint.

Often, as the medication is titrated, the joint reduction occurs spontaneously.

**NOTE:** When benzodiazepines are administered intravenously, appropriate airway and hemodynamic monitoring is required. Moderate (conscious) procedural sedation privileges may also be required (see Chapter 2, Procedural Sedation and Analgesia).

2. If *TMJ* injection is chosen, have the patient open his or her mouth at least 4 cm. Palpate the joint line anterior to the tragus of the ear and the condyle of the mandible located immediately beneath the zygomatic arch. These landmarks are further confirmed by having the patient open and close the jaw while the clinician is palpating the joint line. After preparing the site with povidone-iodine, 3 to 5 mL of lidocaine should be injected into the joint. The needle should be inserted just below the zygomatic arch, one fingerbreadth anterior to the tragus, and directed inward and slightly upward. It will move freely when the tip is in the joint cavity.

**NOTE:** For an acutely painful TMJ, injection with a combination of 0.5 mL corticosteroid and 0.5 mL local anesthetic may be helpful. Joint rest, as described in the "Postprocedure Patient Education" section, may also be helpful.

- 3. The injection of lidocaine alone may allow for spontaneous reduction (Fig. 74-1). Otherwise, a few minutes after the injection, even with bilateral dislocation, the patient might be able to close his or her mouth and retract the mandible into its normal position.
- 4. If passive reduction by muscle relaxation or TMJ injection is unsuccessful, active reduction may be necessary.

#### **Active Reduction**

This technique can be used for unilateral or bilateral dislocation.

- The patient's head should be placed against a wall or high headrest to prevent backward movement. Take care to protect your thumbs because the mandible usually snaps sharply back into place with tremendous pressure, and this is an involuntary reflex. At a minimum, gauze should be wrapped over the gloved thumbs to protect them.
- 2. While standing in front of the patient, have the patient open his or her mouth slightly and place your thumbs on the occlusal surfaces of his or her posterior lower teeth.
- 3. Firmly grasp the mandible on the outside with your fingertips. Exert downward force on the molars (Fig. 74-2) in a slow and firm manner.

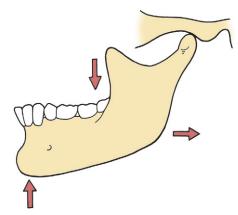

Figure 74-2 Direction of combined forces necessary for reduction.

- 4. For anterior dislocation, after 30 to 60 seconds of downward pressure, apply very light pressure in a posterior direction and elevate the chin. (Pressure should be exerted in the opposite direction for a posterior dislocation.) This light posterior pressure and chin elevation can be accomplished by rotating the posterior or inferior mandible with your fingertips. At this point, the condyles should clear the articular eminence and allow the mandible to slide into its normally closed position (Fig. 74-3). If unsuccessful, this step may be repeated once or twice. With posterior dislocation, because the condyle may have prolapsed into the external auditory canal, baseline hearing should be documented (see Chapter 69, Audiometry).
- 5. Should these procedures fail, attempt to reduce the TMJ under more aggressive procedural sedation (see Chapter 2, Procedural Sedation and Analgesia). Should this also fail, consultation should be considered because reduction may need to be done under general anesthesia.
- 6. If the patient can swing his or her jaw from side to side, the reduction has been successful. Postprocedure radiographs are not required unless the procedure was difficult or traumatic, or there is significant postreduction pain. If the jaw immediately dislocates after successful reduction, a Kerlix-type gauze or a Barton bandage (elastic fabricated bandage) should be wrapped around the jaw and over the top of the head, producing a pressure-type dressing to keep the jaw closed. In this situation, the patient should also be referred to a dentist or an oral or maxillofacial surgeon.

**Figure 74-3** Reduction of a dislocated mandible from a position in front of the patient.

**NOTE:** For recurrent dislocations, search for possible causes (e.g., occlusal disharmony causing muscle spasm, medication-induced trismus, or rheumatoid arthritis).

#### **COMPLICATIONS**

All of the following complications occur only rarely.

- Posterior dislocation of the TMJ from reduction of anterior dislocation, and vice versa.
- Iatrogenic fracture or avulsion of the articular cartilage.
- Anesthesia complications (e.g., allergic reaction to lidocaine).
- Nerve damage.
- Permanent TMJ arthritis related to an improperly managed or undiagnosed condylar fracture; this is particularly a risk if the fracture extends into the articular surface. Prolonged disarticulation (several days) or recurrent disarticulation is also associated with TMJ arthritis.

#### POSTPROCEDURE PATIENT EDUCATION

Patients should be instructed to avoid opening their mouth more than 2 cm (the width of their thumb) for 2 weeks, and they should not yawn widely, take large bites of food, or laugh excessively for 4 to 6 weeks. They should also be placed on a soft diet for 2 weeks, and acetaminophen or nonsteroidal analgesics may be helpful for any discomfort after reduction. Patients should be taught to support the mandible with a hand when they yawn. In some instances, immobilization of the jaw is needed after reduction. For immobilization, refer the patient to a dentist. Some dentists immobilize the jaw for up to 2 weeks to give the stretched muscles and ligaments an opportunity to heal. This also allows the edema to subside. Inadequate immobilization may lead to recurrence of dislocation. If the dislocation was not traumatic, inform the patient that repeating the action that caused it will again cause dislocation. This is particularly true in the 4 to 6 weeks after reduction when the ligaments are not fully healed. Also warn the patient that recurrent dislocations may lead to permanent TMI arthritis. In recurrent TMI dislocation, the patient should be referred and the jaw immobilized for 4 to 6 weeks.

### Three Alternatives to Splint Therapy for a Tender or Clicking Temporomandibular Joint

Patients with a tender or clicking TMJ are frequently referred to a dentist or oral surgeon for internal splinting or "splint therapy." A custom splint is made to be inserted between the upper and lower molars and provide constant tension on the TMJ by separating the molars. Such constant tension and immobilization of the TMJ hopefully allows it to heal. Some primary care clinicians use a "boil and bite" mouthpiece (which can be bought in most sporting goods stores to protect teeth during contact sports) in the same manner. The following exercises have been published as alternatives to splinting. If they fail, rest therapy (as noted in the section to follow) may be an option.

#### Method A

- Have the patient obtain a soft wooden or plastic rod, approximately 15 cm long and 1.5 cm in diameter (e.g., a wooden dowel).
- 2. At least three times a day, the patient should thrust the mandible forward and grasp the rod with his or her back molars.
- 3. For 2 to 3 minutes, the patient then rhythmically bites on the rod with a grinding movement (Fig. 74-4).

#### Method B

 Although it may be initially uncomfortable, this exercise should eventually lead to some relief in uncomplicated TMJ syndrome.

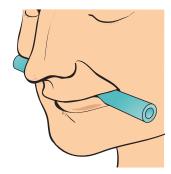

Figure 74-4 Wooden rod chewing exercise.

2. At least four to five times a day, for 15 repetitions, the patient should rhythmically thrust the lower jaw forward and backward, in an anterior-posterior direction. The mouth should be slightly open, and when the exercise is performed correctly, the patient will look like a cheeky schoolchild exposing the bottom lip (Fig. 74-5).

#### Method C

This method consists of six exercises to be repeated six times per day  $(6 \times 6)$ .

**NOTE:** These exercises were recommended by an oral surgeon and should not cause pain while being performed. If performance causes discomfort, the intensity, rather than the number and frequency of the repetitions, should be reduced.

- 1. Have the patient hold the front third of his or her tongue to the roof of the mouth and take six deep breaths.
- 2. Next, have the patient hold his or her tongue to the roof of the mouth and open the mouth six times. The jaw should not click.
- 3. Have the patient hold the chin with both hands, keeping the chin still. Without actually letting it move, the patient should attempt to move his or her chin up, down, and to each side.
- 4. Next, with the chin between the heels of both hands, and the fingertips behind the neck, have the patient pull his or her chin toward the neck. Hold for 6 seconds.
- 5. Next, have the patient push his or her upper lip back as if to push the head straight back while using the neck muscles to *prevent* the head from being pushed back. Hold for 6 seconds.
- 6. To finish the exercises, have the patient pull the shoulders back, as if to touch the shoulder blades together, and hold for 6 seconds.

#### Temperomandibular Joint "Rest" Program

The following instructions may be given to patients:

1. Avoid biting any food with your front teeth—use small, bite-size pieces.

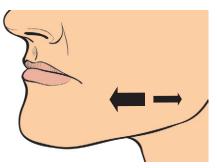

Figure 74-5 Lower jaw thrust exercise.

- 2. Food should be in small enough pieces to avoid opening your mouth wider than the thickness of your thumb.
- Avoid eating food that requires prolonged chewing (e.g., raw vegetables, tough meat, hard crusts of bread).
- 4. Avoid protruding your jaw (e.g., talking, applying lipstick) or your tongue.
- 5. Try to breathe through your nose at all times.
- 6. Do not sleep on your jaw; attempt to always sleep on your back.
- 7. Avoid clenching your teeth—keep your lips together and your teeth apart.
- 8. Avoid chewing gum.
- 9. Always try to open your mouth in a hinge or arc motion.
- Practice a relaxed lifestyle so that your jaws and face muscles feel relaxed.

#### **CPT/BILLING CODES**

- 21480 Closed uncomplicated treatment of temporomandibular dislocation, initial or subsequent
- 21485 Closed complicated treatment of temporomandibular dislocation (e.g., recurrent requiring intermaxillary fixation or splinting), initial or subsequent

### **TYMPANOMETRY**

Gerald A. Amundsen

The tympanometer is a tool that has been used since the 1970s to assist in evaluation of middle ear and eardrum (tympanic membrane) function. Despite the current availability of multiple other tools and measuring instruments, tympanometry, with or without pneumatic otoscopy, continues to be a useful tool in the primary care clinic. The tympanogram, a graphic display of the information obtained from the tympanometer, provides the clinician an ability to objectively evaluate otitis media with effusion, acute otitis media, suspected or known perforation of the tympanic membrane, patency of pressure equalization tubes (PE tubes), ossicular chain function, and suspected eustachian tube dysfunction. When added to the history, clinical signs, and otoscopic findings, a tympanogram usually improves the clinician's diagnostic accuracy as well as his or her ability to monitor treatment.

The tympanometer consists of the probe, which is inserted into the external ear canal, and the associated hardware that produces stimuli (air and sound) to be directed toward the tympanic membrane, measures the response, and records the results. The probe has three ports, each of which has an independent function. The speaker port transmits the tone toward the tympanic membrane, and the air port transfers air to vary the pressure in the canal between the probe tip and the tympanic membrane. The third port has a microphone to gather sound waves reflected from the tympanic membrane. The remaining components of a tympanometer include the air pump, the oscillator (produces the tone transmitted through the speaker port), a manometer, a recorder, and an impedance bridge to translate information received through the microphone.

Ultimately, the tympanometer evaluates *immittance*, a measurement of the performance of the tympanic membrane and the middle ear. *Immittance* is the term used to describe the flow of energy into the middle ear (*admittance*) or the opposition to this flow of energy (*impedance*). The word *immittance* was coined by combining the words *impedance* and *admittance*.

#### **INDICATIONS**

- Any patient with complaints of ear pain, vertigo, or hearing loss
- If patency of PE tubes is in question
- Abnormalities (e.g., fluid, tympanic membrane retraction, perforation) visualized on otoscopic examination
- Possible tympanic membrane perforation (or to follow-up previously diagnosed perforation)
- Eustachian tube dysfunction when the tympanic membrane appears normal on examination
- Persistent middle ear effusion or otitis media with effusion

#### **CONTRAINDICATIONS**

- Fulminant otitis externa
- Occlusion of the canal by cerumen (see Chapter 72, Cerumen Impaction Removal) or a foreign body (see Chapter 76, Removal of Foreign Bodies from the Ear and Nose)
- Age younger than 7 months (relative contraindication)

**NOTE:** Age younger than 7 months is a relative contraindication because although a positive result (type B curve) likely indicates an effusion, a negative result may be falsely negative. Even in the presence of a significant effusion, the soft, highly compliant ear canals in infants may result in a normal tympanogram.

#### **EOUIPMENT**

- Probe covers of various sizes to create a good seal in ear canals of different sizes (universal to all models).
- A tympanometer with air pressure range of -400 to +100 mm  $H_2O$  is preferable. Air pressure is also measured in decapascals (daPa; 1.0 daPa = 1.02 mm  $H_2O$ ).
- Oscillator in tympanometer that produces a tone of 226 cycles per second (hertz [Hz]; 220 Hz is actually optimal).
- Most units, even the hand-held units, have some version of a printer for documentation.
- (Optional) Memory (may store data from one to eight patients, with one or two tests per patient).
- Units range from hand-held models to more expensive models equipped with a graphic acoustic reflex display or the instrumentation to perform audiometry. Although the basic tympanometer is a generally affordable tool for the office, these other features can increase the cost of equipment.

#### PREPROCEDURE PATIENT PREPARATION

After educating the patient about the indication(s) for the procedure, reassure him or her that the process is painless. Describe the tone that may be heard and the slight bursts of air that will be felt in the canal. Emphasize the importance of remaining still during the test to ensure accuracy and ease of data collection.

#### **TECHNIQUE**

 Check the ear canal for patency and visualize the tympanic membrane with the otoscope. At this point, the use of pneumatic otoscopy may improve diagnostic accuracy.

**Figure 75-1** With the patient seated upright, apply traction to the helix and insert the probe.

- 2. Select the probe tip; choose the size that occludes the canal and creates a seal without entering too deeply.
- 3. Place the patient upright in the seated position, or in the lap of a parent in the case of a young child.
- 4. Apply posterior-superior traction to the helix to straighten the ear canal (posterior-inferior traction in the young child), and place the probe into the outer canal (Fig. 75-1).
- Once a seal has been obtained, the tympanometer will automatically deliver the sound, vary the air pressures, and record the various parameters.

#### **COMMON ERRORS**

- Failure to remove cerumen impaction or a foreign body leads to false-positive results (type B curves) or inability to complete the test owing to "occlusion."
- Inappropriate probe tip size leads to "occlusion" or "air leak."

**NOTE:** Typical devices display results on a graphic screen when a test is successfully completed. Error messages such as "occlusion" or "leak" indicate the need for repositioning the probe or selection of a more appropriate tip size. The test will usually not run to completion unless occlusions in the canal have been removed and an appropriate seal has been achieved and maintained.

#### INTERPRETATION

The tympanogram is a graph of middle ear compliance on the vertical axis and pressure on the horizontal axis. From this graph, four useful pieces of information can be obtained for interpretation (Fig. 75-2 and Table 75-1):

• Canal volume is a measurement of the approximate volume between the probe tip and the tympanic membrane. It is usually 0.2 to 2.0 mL, but varies with age and bony structure. Abnormally high volume is indicative of a patent PE tube or a perforation.

TABLE 75-1 Interpretation of the Tympanogram				
Tympanogram Result	Characteristics	Possible Diagnoses		
Туре А	The "normal' curve Peak compliance is at 0 mm H <sub>2</sub> O or daPa	Normal or negative tympanogram		
Type A <sub>D</sub>	Tall peak at <sup>2</sup> 0 mm H <sub>2</sub> O or daPa indicating high compliance	Monomeric (one layer) tympanic membrane due to healing perforation, disruption of the ossicular chain		
Type A₅	Short peak at 0 mm H <sub>2</sub> O or daPa indicating low compliance	Thickened tympanic membrane, ossicular fixation, presence of middle ear fluid		
Туре В	Flat or minimal peak indicating minimal compliance	With low canal volume: Cerumen impaction, foreign body, wrong probe With high canal volume: Pressure equalization tubes, perforation With normal canal volume: middle ear fluid		
Туре С	Peak compliance at negative pressure (<-100 mm H <sub>2</sub> O or daPa)	Retracted membrane, eustachian tube dysfunction with or without effusion		

daPa, decapascals.

Abnormally low volume may indicate obstruction or a bulging tympanic membrane due to effusion.

- Compliance of the tympanic membrane when receiving sound at various pressures. The peak of the curve (maximal compliance) typically occurs when the air pressure is equal on both sides of the tympanic membrane (0 mm H<sub>2</sub>O or daPa).
- Pressure (mm H<sub>2</sub>O or daPa) at which the compliance peaks: usually 0 mm H<sub>2</sub>O, but may be negative with eustachian tube dysfunction or a retracted tympanic membrane, or greater than 0 mm H<sub>2</sub>O or daPa when the membrane is bulging.
- Width of the curve is calculated by the device. This may be too
  wide with early or resolving effusion or tympanosclerosis. This is
  the least useful portion of the data because the result is quite
  variable and the diagnostic reliability for middle ear pathology is
  uncertain.

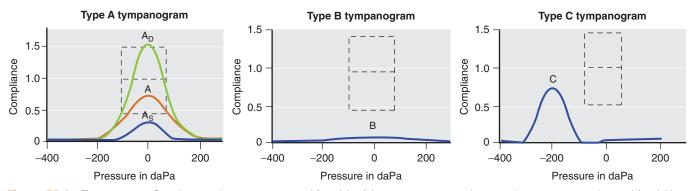

Figure 75-2 Tympanograms. Compliance and pressure are normal for adults if the curve crosses into the rectangles at any point and normal for children younger than 10 years of age if the curve crosses into the lower rectangle. See Table 75-1 for interpretation.

It should be noted that a localized abnormality (e.g., perforation of the tympanic membrane) may obscure the ability to evaluate the rest of the middle ear system. However, compared with pneumatic otoscopy, the tympanogram is usually more accurate: pneumatic otoscopy may elicit movement of a tympanic membrane despite a pinpoint perforation, whereas a tympanogram will likely make the correct diagnosis. In contrast, middle ear mucosal edema may be sufficient to mask even a large perforation on tympanometric evaluation.

#### POSTPROCEDURE PATIENT EDUCATION

The tympanogram is used to help direct treatment and monitor progress. The patient should be informed of the result and treatment plan. Appropriate consultation should be requested when indicated.

# REMOVAL OF FOREIGN BODIES FROM THE EAR AND NOSE

John Harlan Haynes III • Michael Zeringue

The nasal orifice and external auditory canal occasionally collect small objects such as beads, insects, peanuts, pebbles, or beans. Foreign bodies in this area are especially common in pediatric and mentally impaired individuals. Knowledge of the type of foreign body and how long it has been lodged in the orifice is very helpful. If an expandable material is suspected (e.g., organic materials, beans, seeds), irrigation with water or saline may be contraindicated because it may cause additional expansion of the object. Timeliness may be a priority because the object may become more firmly lodged in place as the mucosa swells. Reactive debris may accumulate as a local response to the irritation. Manual removal or suction may be required to remove these objects and the accompanying debris.

Various techniques are available for removing foreign bodies with instruments; however, simple attempts at removal should generally be pursued before instrumentation. In children with a nasal foreign body, a nebulized decongestant can be used to assist expulsion with simple nose blowing. A positive-pressure technique (as in mouth-to-mouth resuscitation) using a pediatric bag valve mask (Ambu bag) may be used in infants and young children. Block the unaffected nostril and, while not exceeding recommended maximal pressure with the bag valve mask (by cardiopulmonary resuscitation guidelines), force air briskly through the oropharynx and out the obstructed nostril to dislodge the object. In older children and adults, vasoconstrictive nasal solutions (e.g., phenylephrine, epinephrine, oxymetazoline) may be used to reduce mucosal edema. Wait 10 minutes after application, then have the patient obstruct one nostril and then blow our forcefully through the other nostril to dislodge the object. Even if the object does not come out, the relaxed and decongested mucosa will give the clinician more room to work.

In the external ear canal, pulsing saline irrigation through an 18-gauge plastic catheter and directing it posteriorly may dislodge the impacted object. If tympanic membrane perforation is suspected, however, irrigation is contraindicated.

The use of strong acrylic glue (cyanoacrylate) has been advocated for removing beads from the nose or external canal but the patient must be able to remain very still. The ultimate goal when removing a foreign body with this technique, as well as with all techniques, is to remove the object with as little trauma as possible and to avoid pushing it further back toward the posterior nasal passage or tympanic membrane. If this technique is to be used, make sure acetone is available to remove any misplaced cyanoacrylate (see section on "Alternate Technique: Glue").

Having acetone available may also be helpful if the foreign body turns out to be chewing gum or polystyrene (e.g., Styrofoam) foam or beads. In addition to dissolving cyanoacrylate glue, acetone has been reported in the literature to dissolve or soften polystyrene; it also reduces the adherence of particles consisting of these substances or gum. Ethyl chloride has been used in the same manner. It should be noted that there have been no studies regarding any possible

toxicity from acetone, dissolved polystyrene, or ethyl chloride in contact with a mucous membrane. Therefore, only a few drops of the acetone or ethyl chloride should be dripped directly onto the foreign body under guidance with an otoscope. After being left in place for 5 minutes or less, the resulting combination should be removed with forceps, suction, or irrigation. Ultimately, the ear should be irrigated to remove any residual chemicals after the object is removed. If there is a possibility or a history of a perforated tympanic membrane, this process is contraindicated.

Both reassurance and immobilization are important in manual removal of nasal or external canal foreign bodies. Availability of the proper tools and an adequate light source are also critical. To minimize the risk of lacerations or abrasions, all attempts to remove foreign bodies should be made under direct visualization with magnification if at all possible. The clinician should set realistic limits on the amount of time to be spent and number of attempts to be made. Referral to an ear, nose, and throat (ENT) specialist may be prudent (1) if the examiner is dealing with an expandable material (unless there is a high probability of successful removal); (2) when the nasal passage or external ear canal is completely occluded and surrounded by marked edema and inflammation; (3) if the object is adherent or adjacent to the tympanic membrane; or (4) if attempts to remove the object have been unsuccessful or will worsen the scenario. For such difficult removals, local anesthesia, conscious sedation, or even general anesthesia may be necessary. If an ENT specialist agrees, and if the patient is in considerable pain, instillation of topical anesthetic drops before transportation may be appreciated.

NOTE: Miniature button or disk batteries are commonly used in watches, calculators, cameras, hearing aids, travel clocks, and even greeting cards that play music. Consequently, they are frequently found as foreign objects in noses and ears. Removal is a high priority because permanent damage can result (usually localized electrical burns, but bone and cartilage can be destroyed) if they are allowed to remain for more than a short time. Although miniature batteries contain toxic heavy metals such as mercury and other poisonous substances, their greater danger lies in the fact that they can produce electrochemical current. They should be removed promptly, and irrigation, nose drops, or eardrops are strictly contraindicated.

**NOTE:** If a recent foreign body turns out to be a moth, take the patient into a dark room and shine a flashlight into the ear or nose. The moth will likely fly out toward the light!

#### **INDICATION**

A known foreign body is the indication for treatment.

**NOTE:** A general rule for foreign bodies in the ear is that if the object is in the outer two thirds of the canal and is easily accessible,

it can usually be removed. If it is closer to the eardrum and cannot be removed by irrigation, referral should be considered.

#### **CONTRAINDICATIONS**

Consider referral if any of the following contraindications apply.

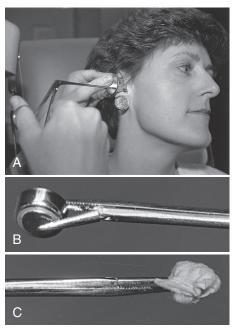

- Lack of knowledge of normal anatomy of nasal passage or external ear canal.
- Nasal passage or external ear canal is obscured because of trauma. With a foreign body that has perforated the tympanic membrane, removal may cause further damage to the tympanic membrane, possible damage to middle ear ossicles, as well as loss of hearing.
- The airway is in danger from a nasal foreign body.
- A large foreign body is impaled into the external ear canal.
- The patient is uncooperative and cannot be sedated (see Chapter 7, Pediatric Sedation and Analgesia) or anesthetized (see the section on "Anesthesia for Auditory Canal" and Chapter 4, Local Anesthesia, Chapter 9, Oral and Facial Anesthesia, and Chapter 10, Topical Anesthesia).
- For a miniature battery, do not use nose or ear drops.
- For organic or expandable materials, unless the clinician is fairly certain of a successful removal, flushing with saline or water is contraindicated. Flushing can hasten or enhance the swelling.
- Irrigation is contraindicated with an acute or chronic ruptured tympanic membrane.
- For other contraindications to removal from ear, see Chapter 72, Cerumen Impaction Removal.

#### **EOUIPMENT**

- Traditional foreign body extraction tools such as a Frazier suction tip; ear curette (Fig. 76-1) or wire loop curette; nasal bayonet (see Fig. 76-1), alligator (Fig. 76-2; see Fig. 76-1), or Hartmann forceps; fine tissue or Adson forceps; right-angle hook (can be made from 21-gauge needle; Fig. 76-3) or ball-tipped right-angle hook.
- Cotton-tipped swabs.
- Nasal or ear speculum (select the largest that will fit the orifice or canal; visibility and room for instrumentation is better with a speculum than with an otoscope).
- Magnification, in the form of either an otoscope with an operating head or a loupe.
- Bright light that can be directed or focused. If a headlamp is available, both hands will be free to perform the procedure.
- Topical anesthetic such as 2% to 5% lidocaine (see the section on "Anesthesia for Auditory Canal" and see Chapter 10, Topical Anesthesia). Benzocaine spray (14%, Cetacaine) can be used for

**Figure 76-1** Traditional instruments used for foreign-body extraction: Ear curette (top), nasal (bayonet) forceps (middle), and alligator forceps (bottom).

**Figure 76-2** Alligator forceps (**A**) for retrieving small batteries (**B**) and paper balls (**C**) from auditory canal.

nasal anesthesia; 20% benzocaine solution can be used for the external ear canal.

- For a local field ear block, use a 27-gauge, 1½-inch needle. An anesthetic such as 1% lidocaine with epinephrine can be used on the external canal. For subcutaneous injections deeper inside the canal, plain 2% lidocaine may be useful (see also Chapter 4, Local Anesthesia, and Chapter 9, Oral and Facial Anesthesia). Adding a 1:10 mixture of 8.4% sodium bicarbonate to lidocaine helps reduce the pain of injection.
- Nasal decongestant such as phenylephrine (0.25% to 2%; Neo-Synephrine, Vicks), epinephrine (1:50,000; Adrenalin), or oxymetazoline hydrochloride (0.05%; Afrin, Neo-Synephrine 12 hour) spray. An atomizer is helpful if available.
- Irrigant such as saline.
- Wall or portable suction unit.
- Equipment necessary for clinician to follow universal blood and body fluid precautions, especially when working near mucous membranes of a patient.
- Strong magnet and magnetizable nail for retrieving metal foreign bodies.
- Irrigation equipment (e.g., surgical Chux, kidney basin) as noted in Chapter 72, Cerumen Impaction Removal.
- Optional: 2- to 6-Fr diameter Fogarty (biliary or cardiovascular), Foley, Swan-Ganz or Schuknecht FB catheter, or Katz oto-rhino foreign body remover (single-use balloon-tipped catheter attached

**Figure 76-3** Precise right-angle hook made from bending a  $1\frac{1}{2}$ -inch, 21-gauge needle tip at a right angle is an excellent tool for removing smooth objects such as beans and corn kernels.

- to syringe). The balloons on the Fogarty, Foley, or Swan-Ganz catheters will need to be inflated with a 2-mL syringe.
- Optional: Commercially available, single-use, disposable, Hognose (4-, 5-, or 6-mm) or Gatornose (small or large) otoscope tip.
- Alternate technique, suction: 30-inch plastic intravenous extension tubing or 10-Fr suction catheter, heat source (e.g., burner, alcohol lamp, lighter), blunt end of metal ear curette handle or atomizer tip, and hemostat.
- Alternate technique, glue: Dacron-tipped applicator, thin paintbrush, plastic ear curette, straightened paperclip, toothpick, or the wooden end of cotton-tipped swab and strong acrylic glue (cyanoacrylate; Dermabond or Superglue), with acetone to remove the glue if necessary.

#### PREPROCEDURE PATIENT PREPARATION

- Stress the importance of remaining immobile during the procedure.
- For nasal or otic foreign body removal, discuss the chance of minor trauma. This may be associated with discomfort during the procedure or some bleeding after the procedure.
- For nasal foreign bodies, the risk of aspiration should be discussed.
- For ear irrigation or instrument removal, discuss the risk of perforation and dizziness.
- Alternatives, risks, and benefits should be explained and informed consent obtained.
- If instrumentation is to be performed, after the topical anesthetic is applied, touch the mucosa with the instrument slightly inside the orifice so that the patient knows what to expect and to avoid being startled.

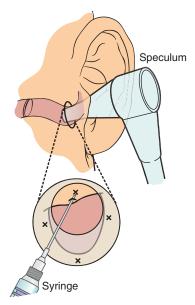

#### **TECHNIQUE: NASAL FOREIGN BODY**

- 1. Topical anesthesia and vasoconstriction can be applied as a spray or with drops (e.g., a mixture of 2% to 5% lidocaine and 0.25% to 2% phenylephrine hydrochloride or 0.5% oxymetazoline hydrochloride). After waiting a few minutes for the mixture to work, carefully examine the nostril and determine the best instrument or technique. Alternatively, the decongestant can be sprayed first; after waiting a few minutes for the decongestant to work, if the topical anesthetic is then sprayed, it may last longer. The disadvantage of spraying the decongestant and topical anesthetic separately is that the clinician then has to wait a few more minutes for the topical anesthetic to work.
- 2. The patient may be sitting or lying. Extend the patient's head. Apply pressure on the tip of the nose in a superior and posterior direction to help visualize the nasal canal. Irrigation should not be used in the nasal cavity because it may push the object into the oropharynx or larynx, causing aspiration.
- 3. Smooth, round objects can be removed using suction or right-angle hooks. For the right-angle hook, slide it past the object with the tip parallel to the nasal sidewall. Once it has passed the object, rotate it 90 degrees so that the tip is behind the object, and then gently pull the object out.
- 4. An alligator or bayonet forceps may be used to grasp an object that has a small leading edge.
- 5. A lubricated, small Fogarty, Foley, Swan-Ganz, or Schuknecht FB catheter, or a Katz oto-rhino foreign body catheter can be passed beyond the foreign body. After inflating the balloon or opening the umbrella, gentle traction will either facilitate removal or stabilize the foreign body to prevent oropharyngeal aspiration. This technique may slightly increase the risk of trauma and epistaxis; it is rare to visualize much of the catheter tip during insertion.
- 6. In all cases, instruments introduced into the nasal passage require a steady hand resting on the patient's head in case of sudden movements, which can be involuntary if pain is elicited.
- 7. After removal, examine the orifice closely to make sure that another foreign body was not behind the first and that all

debris has been removed. Any particles left behind can lead to irritation, inflammation, drainage, or chronic granulation. Also check the unaffected nasal and ear orifices for any other surprises.

#### **TECHNIQUE: OTIC FOREIGN BODY**

- Many clinicians perform hearing testing (see Chapter 69, Audiometry) to determine the baseline before inserting instruments.
   Some also perform tonometry (see Chapter 68, Tonometry) to attempt to determine if the tympanic membrane has been perforated.
- 2. Small children may need to be sedated (see Chapter 7, Pediatric Sedation and Analgesia). If an attempt is to be made without sedation, they may want to sit on the lap of a parent or attendant with the ear facing the clinician. Adults usually want to remain seated with the affected ear facing the clinician. The patient may also be comfortable lying down with the affected ear facing upward.
- 3. With the ear turned upward, instill a topical anesthetic. After several minutes, use suction to remove pus, topical anesthetics, or blood as necessary to visualize the object. The patient should be warned that suction can be very loud.
- 4. With adults, visualization of the external ear canal is aided by pulling the auricle upward and backward to straighten the canal. In small children, the auricle is pulled downward. If an instrument is to be used, it should be used only under direct visualization. Insert it slightly inside the auricle, at first, to help the patient accommodate to the noise and sensation of instrumentation. Compared with the internal canal, the external third of the canal has a thicker layer of skin and subcutaneous tissue that covers cartilage; the internal two thirds has a thinner, more fragile layer of skin covering only bone.
- 5. The depth and surface qualities of the object usually suggest which tool(s) to use. Grasp fibrous objects (e.g., cotton, plant matter) with the alligator forceps (see Fig. 76-2). Smooth objects (e.g., beans, seeds, popcorn kernels) that are blocking no more than half the diameter of the canal might be dragged out by passing an ear curette or wire loop beyond the object and gently withdrawing it. Larger, smooth, and hard items such as small batteries and BBs may be teased out with a fine, 1-mm, right-angle hook (see Fig. 76-3) or ball-tipped right-angle hook. Slide the right-angle hook past the object with the tip parallel to the canal sidewall. Once it has passed the object, rotate it 90 degrees so that the tip is now behind the object, and gently pull the object out. Objects with sharp projections, such as earrings and screws, may need to be grasped with forceps to avoid laceration of sensitive membranes.
- 6. Irrigation may move a foreign body far enough away from the eardrum to increase the chance of extraction.
- 7. Occasionally, iron-containing items such as a BB can be removed with a small magnet probe. A probe can be fashioned from a nail that has been blunted and magnetized by drawing it across any strong permanent magnet. Permanent magnets are available in hardware stores or can be found in the rear of stereo speaker cones.
- 8. Irrigation may be useful in certain instances after object removal, such as when small fragments of debris remain.
- 9. Insects in the auditory canal should be drowned or smothered by instilling lidocaine or a benzocaine solution. The liquid kills the insects, which halts their disturbing and painful movements. An alligator forceps can then be used to grasp and remove the insect. Suction can also be used to remove both the insect and the liquid. Some clinicians suggest that mineral oil immobilizes insects faster; however, mineral oil does not provide anesthesia for the patient, and other clinicians say mineral oil is more likely to cause the insects to break into fragments during attempts to remove them.

**Figure 76-4** Four-quadrant field block anesthesia of the external auditory canal. Local anesthetic is injected subcutaneously in the four quadrants of the lateral portion of the ear canal. The largest speculum that will fit is used to guide the injections. The speculum is withdrawn slightly, tilted toward each of the four quadrants, and the needle is inserted subcutaneously (x). A very small amount of anesthetic (0.25 to 0.5 mL) is injected to produce a slight bulge in the soft tissue. A total of 1.5 to 2 mL of anesthetic is usually sufficient to anesthetize the ear canal and permit painless removal of a foreign body. (Riviello RJ: Otolaryngologic procedures. In Roberts JR, Hedges JR [eds]: Clinical Procedures in Emergency Medicine, 4th ed. Philadelphia, Saunders, 2004, pp 1280–1316.)

- 10. In all situations, instruments introduced into the auditory canal require a steady hand resting on the patient's head in case of sudden movements, which can be involuntary if pain is elicited.
- 11. Light, moderate (e.g., intramuscular or intravenous), or general anesthesia may be needed to remove foreign bodies in individuals who cannot tolerate instrumentation with or without local agents. Field block anesthesia of the external auditory canal may be helpful, if tolerated (Fig. 76-4).
- 12. After removal, make sure that another foreign body is not behind the first and that all debris has been removed. Any particles left behind can lead to irritation, inflammation, drainage, or chronic granulation. Some clinicians repeat hearing tests after removing a foreign body to compare with baseline. Also check the unaffected nasal and ear orifices for any other surprises.

#### **ALTERNATE TECHNIQUE: SUCTION**

Suction is especially useful for removing round foreign bodies from the ear or nasal cavity.

- 1. Cut off the tip of the tubing or suction catheter (Fig. 76-5A). Heat the end of the curette handle or metal atomizer tip (Fig. 76-5B). Flange the cut tube end with the preheated handle or tip so that it molds to the blunt, rounded metal (Fig. 76-5C and D). An alternative to this self-made catheter is the commercially available Hognose otoscope tip.
- 2. Clamp the tubing with a hemostat and attach the opposite end to the suction unit (Fig. 76-5E). Alternatively, apply low to medium suction to the Hognose suction line.
- Gently insert the flanged end into the orifice containing the foreign body under direct visualization and advance it to the object.

- 4. When the flange is in contact with the object, quickly unclamp the suction catheter tubing (Fig. 76-5F) and apply full suction immediately through the suction cup onto the foreign object. Alternatively, using the Hognose otoscope tip, apply suction when the soft tip is in contact with the object.
- 5. While suctioning, gently extract the tubing and the suction-attached foreign body (Fig. 76-5G).

#### **ALTERNATE TECHNIQUE: GLUE**

This technique is especially useful for removing smooth, round objects that are difficult to grasp (e.g., plastic beads) from the nasal cavity or ear. It may be more useful in adults because cooperation is required.
